KEY POINTS

- Among adults with MRD-positive ALL in hematologic remission after chemotherapy, 78% achieved a complete MRD response with blinatumomab.

- Complete MRD response after blinatumomab treatment in this population was associated with significantly improved OS.

Approximately 30% to 50% of adults with acute lymphoblastic leukemia (ALL) in hematologic complete remission after multiagent therapy exhibit minimal residual disease (MRD) by reverse transcriptase–polymerase chain reaction or flow cytometry. MRD is the strongest predictor of relapse in ALL. In this open-label, single-arm study, adults with B-cell precursor ALL in hematologic complete remission with MRD ($\geq 10^{-3}$) received blinatumomab 15 $\mu\text{g}/\text{m}^2$ per day by continuous IV infusion for up to 4 cycles. Patients could undergo allogeneic hematopoietic stem-cell transplantation any time after cycle 1. The primary end point was complete MRD response status after 1 cycle of blinatumomab. One hundred sixteen patients received blinatumomab. Eighty-eight (78%) of 113 evaluable patients achieved a complete MRD response. In the subgroup of 110 patients with Ph-negative ALL in hematologic remission, the Kaplan-Meier estimate of relapse-free survival (RFS) at 18 months was 54%. Median overall survival (OS) was 36.5 months. In landmark analyses, complete MRD responders had longer RFS (23.6 vs 5.7 months; $P = .002$) and OS (38.9 vs 12.5 months; $P = .002$) compared with MRD nonresponders. Adverse events were consistent with previous studies of blinatumomab. Twelve (10%) and 3 patients (3%) had grade 3 or 4 neurologic events, respectively. Four patients (3%) had cytokine release syndrome grade 1, $n = 2$; grade 3, $n = 2$), all during cycle 1. After

treatment with blinatumomab in a population of patients with MRD-positive B-cell precursor ALL, a majority achieved a complete MRD response, which was associated with significantly longer RFS and OS compared with MRD nonresponders. This study is registered at www.clinicaltrials.gov as #NCT01207388. (*Blood*. 2018;131(14):1522-1531)

Introduction

Preemptive treatment of malignant disease after remission in patients with low but measurable disease may prolong overall survival (OS) compared with treatment of overt relapse.¹ In acute lymphoblastic leukemia (ALL), minimal residual disease (MRD) is defined as the presence of leukemic cells not detectable by microscopy and may be measured by standardized methods with a sensitivity of 10^{-4} (ie, 0.01%).²

Despite intensive induction/consolidation chemotherapy with hematologic complete remission (CR) rates of 80% to 90%, approximately 30% to 50% of adult patients with ALL and 10% to 20% of pediatric patients with ALL in CR exhibit MRD.³⁻⁸ MRD persistence or recurrence indicates resistance to standard chemotherapy and is the most important risk factor for

hematologic relapse in T-cell and B-cell ALL.⁹⁻¹³ For adult patients, 5-year hematologic relapse rates range from 56% to 100% for MRD positivity, compared with 18% to 33% for MRD negativity.^{4,5,14} Up to 70% of patients have an MRD level $>10^{-3}$ after achieving CR, and their median duration of hematologic remission is 4.9 months.⁵ A meta-analysis of 16 studies, comprising 2076 adults with ALL, concluded that MRD negativity was associated with 10-year event-free survival of 64% vs 21% for MRD positivity (hazard ratio [HR], 0.28; 95% Bayesian credible interval, 0.24-0.33); MRD negativity was also associated with improved OS (HR, 0.28; 95% Bayesian credible interval, 0.20-0.39).¹³

No standard therapy has been defined for ALL with detectable MRD during or after intensive, multiagent chemotherapy.^{2,10}

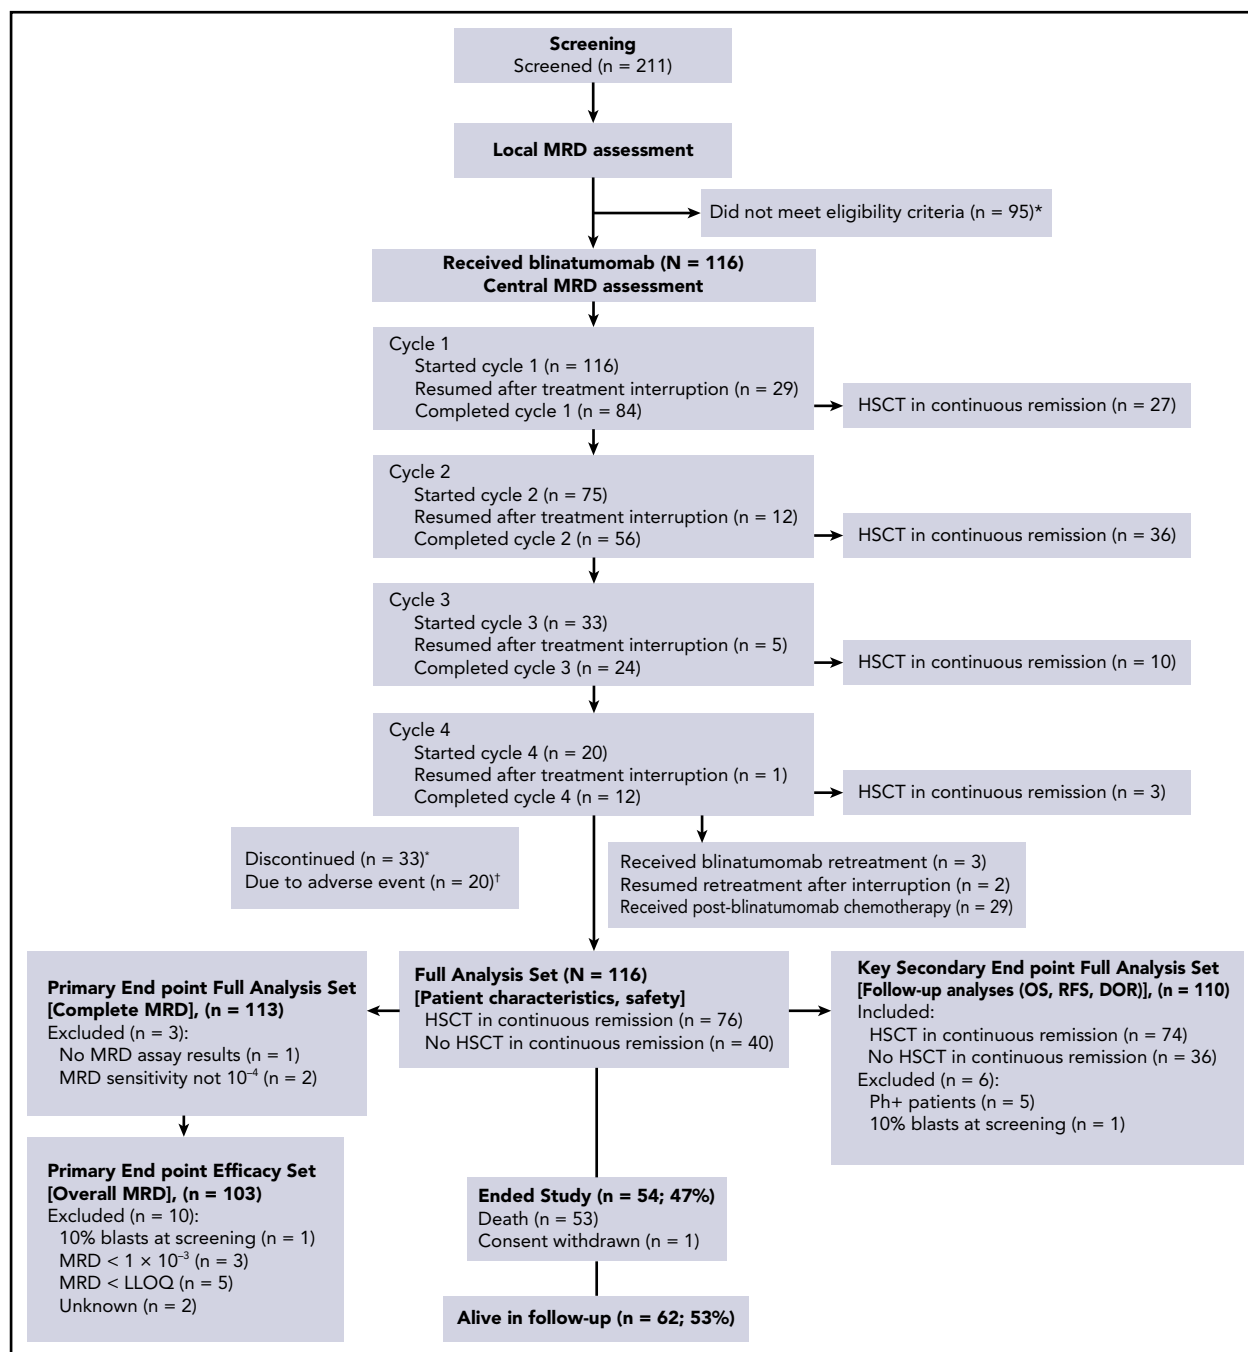

Figure 1. Disposition of patients in the study. *Reasons for not meeting eligibility criteria included: MRD level lower than the required $\geq 10^{-3}$ (therefore, inclusion criterion not fulfilled because disease burden too low; $n = 48$); not in hematologic CR (ie, overt relapse; $n = 31$); technical ($n = 5$); central nervous system relapse ($n = 2$); active infection ($n = 2$); alternative therapy ($n = 2$); neurologic disorder ($n = 2$); CD19⁻ ($n = 1$); hepatic disorder ($n = 1$); and consent withdrawn ($n = 1$). †Reasons for discontinuation ($n = 33$) included: adverse event ($n = 20$ [17.2%]), disease relapse ($n = 10$ [8.6%]), physician decision ($n = 2$ [1.7%]), and other ($n = 1$ [0.9%]). DOR, duration of hematologic remission; LLOQ, lower limit of quantitation; RFS, relapse-free survival.

Study groups and expert guidelines recommend allogeneic hematopoietic stem-cell transplantation (HSCT).^{7,15} Patients with persistent MRD who undergo HSCT have better outcomes compared with those who do not undergo HSCT.^{5,8} However, many patients experience relapse while awaiting HSCT, and detectable MRD pretransplantation is associated with a higher relapse rate after HSCT.^{16,17}

Targeted agents with alternative mechanisms of action may reduce MRD and delay or prevent hematologic relapse.

Blinatumomab is a bispecific T cell-engager antibody construct that directs T cells to CD19⁺ cells.¹⁸ CD19 is expressed on blast cells in >95% of cases of B-cell precursor ALL.¹⁹ In a randomized phase 3 trial of patients with Ph-negative relapsed or refractory B-cell precursor ALL, 44% of 271 patients achieved hematologic CR with blinatumomab, compared with 25% of 134 patients with standard-of-care chemotherapy.²⁰ On the basis of a phase 2 pilot study in MRD-positive ALL with an 80% MRD response rate,²¹ the single-arm, open-label study reported here evaluated efficacy

and tolerability of single-agent blinatumomab in adult patients with ALL in hematologic CR with MRD $\geq 10^{-3}$. In contrast to the pilot study,²² the level of MRD had to be higher in our study ($\geq 10^{-3}$ vs $\geq 10^{-4}$), and a relevant proportion of patients with MRD⁺ ALL after relapse were included.

Patients and methods

Study design

This open-label, single-arm phase 2 study was conducted at 46 centers in Europe and Russia (supplemental Table 1, available on the *Blood* Web site). Patients received blinatumomab 15 $\mu\text{g}/\text{m}^2$ per day by continuous IV infusion for up to 4 cycles. Each cycle comprised 4 weeks of blinatumomab infusion followed by a 2-week treatment-free period. Patients could undergo HSCT any time after cycle 1 at the investigator's discretion. Prophylaxis for central nervous system ALL was recommended before cycle 1 and after cycles 2 and 4. Corticosteroid pretreatment for prophylaxis of neurologic events and cytokine release syndrome was required (supplemental Methods B). Guidelines for supportive care, dose interruption and discontinuation for adverse events, and blinatumomab retreatment for MRD relapse within 18 months are provided in supplemental Methods C. Concurrent antileukemic therapy was prohibited.

MRD evaluation (supplemental Figure 1) for eligibility was performed mostly in the central reference laboratory (University of Kiel, Kiel, Germany) or in national reference laboratories using real-time quantitative polymerase chain reaction of clonally rearranged immunoglobulin and/or T-cell receptor gene rearrangements or using flow cytometry. The central reference laboratory exclusively performed MRD assessments at baseline, at the end of each treatment cycle, and during efficacy follow-up using real-time quantitative polymerase chain reaction.⁴ A complete MRD response was defined as no target amplification with a minimum sensitivity of 10^{-4} .²³ An MRD response was defined as either a complete MRD response or MRD response, which included patients with complete MRD response and those with detectable MRD $< 10^{-4}$.

Patients

Eligible patients were age ≥ 18 years with B-cell precursor ALL in first or later hematologic CR and with persistent or recurrent MRD $\geq 10^{-3}$ after a minimum of 3 blocks of intensive chemotherapy. Full eligibility criteria are provided in supplemental Methods A. Study procedures were approved by the investigational review board at each study center and by independent ethics committees per local regulations. Patients provided written informed consent. The study was registered with ClinicalTrials.gov (#NCT01207388) and EudraCT (#2010-018314-75). This analysis reflects all patients with a data cutoff date of 5 August 2015, when all patients had either completed at least 18 months of follow-up or discontinued the study.

Outcomes

Analysis sets are summarized in supplemental Table 2. For the analyses, different data sets were defined per protocol. This was necessary because some patients who were treated in the study fulfilled the inclusion criteria per local MRD testing, but these criteria were not confirmed after central review, or they had Ph⁺ disease or were not in remission (Figure 1). Reporting of patient characteristics and safety end points used the intent-to-treat

Table 1. Baseline demographics and disease characteristics (full analysis set)

*One patient was ineligible (hematologic relapse).

†Nine patients had MRD levels $\geq 10^{-1}$ with bone marrow cytology in central reference laboratory showing $< 5\%$ blasts.

‡Missing MRD assay results in central reference laboratory (n = 1); MRD quantification at baseline but with subsequent assessments (n = 1).

full analysis set (N = 116). The primary end point was the rate of complete MRD response after cycle 1 among patients in the primary end point full analysis set (n = 113), which excluded patients from the full analysis set with either no central MRD assay results or a test sensitivity that did not reach 10^{-4} . Overall MRD response was evaluated among patients in the primary end point efficacy set (n = 103), which excluded in addition patients from the primary end point full analysis set without hematologic CR or with MRD $\leq 10^{-3}$ at study entry. Thus, the primary end point efficacy set represents the originally intended study population. The key secondary end point, hematologic relapse-free survival (RFS) at 18 months after initiation of blinatumomab, was evaluated among patients in the key secondary end point full analysis set (n = 110), which excluded patients from the full analysis set who had either Ph-positive disease or $\geq 5\%$ bone marrow blasts at study entry. For the primary analysis of RFS, patients were censored at the time of HSCT in continuous CR or at the time of chemotherapy after blinatumomab to focus on patients who were not eligible for HSCT. A sensitivity analysis of RFS not censored at HSCT or chemotherapy was also pre-specified. All other analyses of secondary end points, such as

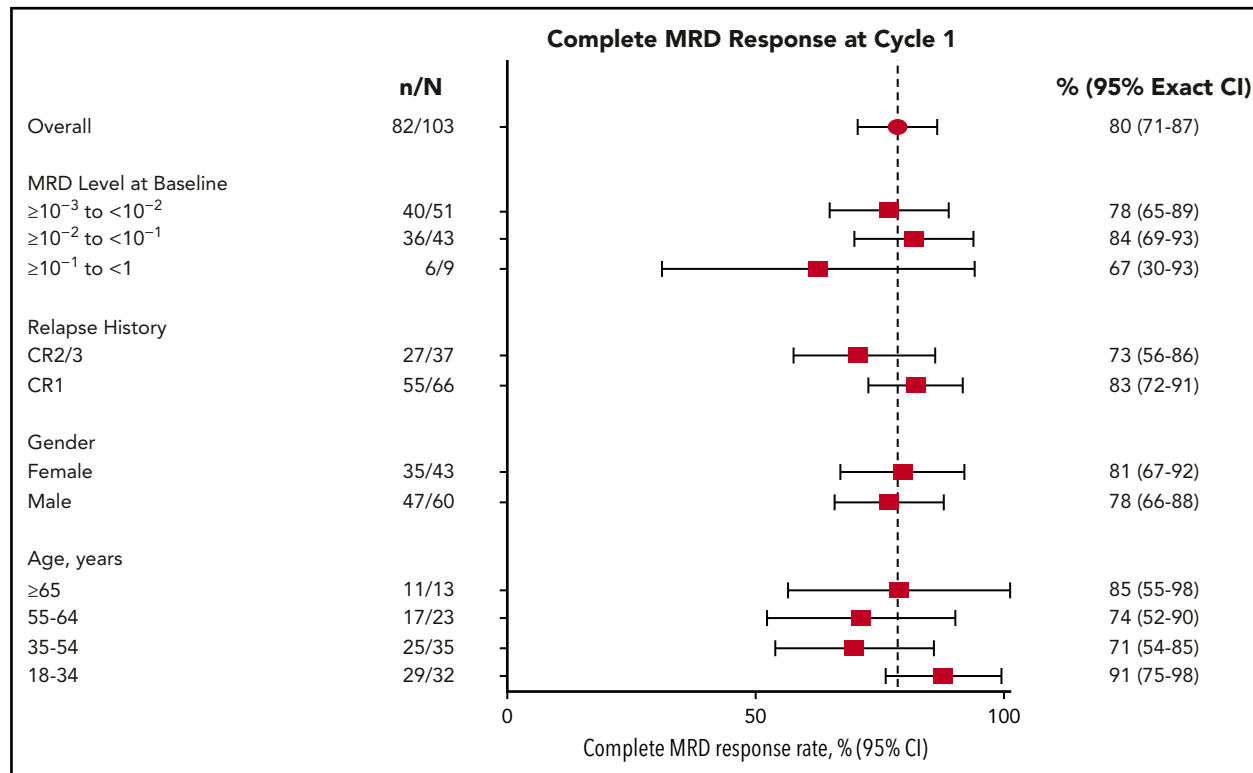

Figure 2. Complete MRD response after cycle 1 by clinical characteristics at baseline and conduct of therapy in cycle 1 (primary end point efficacy set). Three (75%) of 4 patients (95% CI, 19% to 99%) with Ph⁺ ALL and 2 (50%) of 4 patients (95% CI, 7% to 93%) with t(4;11) and/or MLL-AF4⁺ disease had a complete MRD response during cycle 1. MRD complete response rates were similar for patients with or without treatment interruptions during cycle 1. CR1, first CR; CR2/3, second or third CR.

landmark analysis of OS or duration of hematologic remission, were performed without censoring for HSCT or chemotherapy after blinatumomab.

Adverse events from the date of informed consent until 30 days after the last blinatumomab infusion were graded per Common Terminology Criteria for Adverse Events (version 4.0). For patients with HSCT within 30 days after the last dose, the final safety follow-up visit was performed as close as possible before initiation of transplantation conditioning. Adverse events occurring >30 days after treatment were recorded only if the investigator considered the adverse event possibly related to blinatumomab treatment.

Statistical analysis

Complete MRD response rates were calculated using 2-sided exact 95% confidence intervals (CIs) for all patients and in subgroups defined by baseline covariates. Kaplan-Meier estimates with 2-sided 95% CIs were used to describe RFS and OS; differences between subgroups were evaluated using log-rank test. Transplantation effects on long-term outcomes were evaluated in a post hoc analysis considering the waiting time for HSCT. Duration of hematologic remission was estimated by the 1 – cumulative incidence function of relapse, with death in CR as a competing event. Kaplan-Meier estimates of OS and RFS were repeated separately among patients who received >1 cycle or only 1 cycle of blinatumomab. For all Kaplan-Meier tests, censoring for HSCT or postblinatumomab chemotherapy was performed only if specifically stated.

Analysis of the primary and key secondary end points was hierarchical. One hundred evaluable patients would provide 90%

power to demonstrate that a 97.5% 1-sided CI excluded 44% if the true unknown response rate was 61%.

For the key secondary end point, 100 patients provided 90% power to show that the lower boundary of the 95% CI for the Kaplan-Meier RFS rate (with censoring of patients at HSCT) would exceed 28%, assuming a true hematologic relapse rate at 18 months of 55% and an HSCT availability rate of $\leq 67\%$.

The statistical analysis plan predefined analysis sets that were based on availability of MRD data and patient population. The main outcome parameters (patient characteristics and safety) were analyzed in the intent-to-treat full analysis set (N = 116); the primary end point was analyzed in the primary end point full analysis set (n = 113); the secondary end points (OS, RFS, and duration of hematologic remission) were analyzed in the secondary end point full analysis set (n = 110). Overall MRD response was evaluated in the primary end point efficacy set (n = 103). Additional details on the definition and composition of data sets are given in Figure 1 and supplemental Table 2.

RFS, OS, and duration of hematologic remission were also calculated in landmark analyses beginning at day 45 for patients with or without a complete MRD response within cycle 1. Day 45 was selected for these analyses because it was the end of cycle 1, when the last MRD assessment was performed. RFS was defined as time from first blinatumomab dose to the earlier of first detection of hematologic/extramedullary relapse, secondary leukemia, death (resulting from any cause), or, if applicable, last date of continuous CR.

Role of the funding source

The trial was designed by Amgen Research (Munich), GmbH (formerly Micromet AG), in collaboration with the trial investigators. The first author prepared the first draft of the manuscript, with assistance from professional medical writers who were funded by Amgen. All authors had access to the data and provided contributions to subsequent drafts of the manuscript. All authors vouch for the integrity and completeness of the data and for the fidelity of the trial to the protocol. Statisticians employed by Amgen conducted the statistical analyses and contributed to the manuscript. An independent data and safety monitoring board met regularly to review safety and efficacy data to provide recommendations for safety oversight and protection of the scientific integrity of the study.

Results

Patient characteristics

The full analysis set for patient characteristics included 116 patients who received at least 1 blinatumomab infusion between November 2010 and February 2014 (Figure 1). Median age was 45 years (range, 18-76 years). Forty-seven percent of patients were enrolled with MRD $\geq 10^{-2}$, and 35% were in second or later hematologic CR (Table 1). All patients completed the treatment

period (Figure 1). Overall, 76 patients underwent HSCT in continuous CR after 1 (n = 27), 2 (n = 36), or 3 to 4 cycles (n = 13; Figure 1). Treatment cycles, interruptions, and withdrawals are summarized in supplemental Results A.

Primary end point: MRD response

The primary end point full analysis set for analysis of a complete MRD response included 113 patients with evaluable MRD markers (supplemental Table 2). Of these patients, 88 (78%) achieved a complete MRD response after cycle 1. The lower bound of the 95% CI (69% to 85%) was $>44\%$, confirming the study hypothesis. Two additional patients achieved a complete MRD response after cycle 2; no additional patient achieved a complete MRD response after cycle 3 or cycle 4. Among 5 patients with Ph⁺ disease who had MRD evaluations, 3 (60%) had an MRD response during cycle 1.

The primary end point efficacy set for analysis of overall MRD included 103 patients in hematologic CR and with MRD $>10^{-3}$ at baseline. Of these patients, 91 (88%) achieved any MRD response, including 82 (80%; 95% CI, 71% to 87%) with a complete MRD response after cycle 1. Complete MRD response rates were similar between patients with MRD $\geq 10^{-2}$ and those with MRD $<10^{-2}$ at baseline and between patients with first remission and

Figure 3. RFS and OS among Ph-positive patients in hematologic CR at start of treatment (key secondary end point full analysis set). (A) RFS without censoring at allogeneic HSCT or postblinatumomab chemotherapy. Median follow-up, 29.9 months. (B) RFS by remission status at screening without censoring at allogeneic HSCT or postblinatumomab chemotherapy. Complete MRD response was defined as MRD negativity with minimum sensitivity of 10^{-4} . (C) OS without censoring at allogeneic HSCT or postblinatumomab chemotherapy. Median follow-up, 30.0 months. (D) OS by complete MRD responder status in cycle 1 among evaluable patients (landmark analysis, excluding patients who were censored or had relapsed or died within 45 days of beginning treatment), without censoring at allogeneic HSCT or postblinatumomab chemotherapy. (E) RFS without censoring at allogeneic HSCT or postblinatumomab chemotherapy by complete MRD responder status in cycle 1 and salvage status among evaluable patients (landmark analysis, excluding patients who were censored or had relapsed or died within 45 days of beginning treatment). NR, not reached.

those with later remission at baseline (Figure 2). Of 45 patients in this analysis set with treatment interruptions as a result of any cause during cycle 1, 37 (82%) achieved a complete MRD response.

Secondary efficacy end points: survival and transplantation

The key secondary end point full analysis set included 110 patients from the full analysis set who had Ph⁻ disease and <5% blasts at baseline. Among these patients, the Kaplan-Meier estimate for RFS at 18 months was 54% (95% CI, 33% to 70%), exceeding the prespecified boundary of 28% and thereby meeting the key secondary end point. Estimates of RFS at 18 months were similar with or without censoring for post-blinatumomab HSCT and chemotherapy. Median RFS was 18.9 months (95% CI, 12.3-35.2 months), with a median follow-up of 29.9 months (Figure 3A). Median RFS was 11.0 vs 24.6 months among patients treated within later CR vs first CR (unadjusted HR, 2.09; 95% CI, 1.26-3.48; $P = .004$; Figure 3B). Patients in first CR also had improved OS compared with those in later CR (supplemental Figure 2). The impact of other baseline covariates on OS, RFS, and duration of hematologic remission is summarized in supplemental Table 3.

Forty-eight of 110 patients remained in CR (36 after subsequent HSCT), 38 experienced relapse in CR, and 24 died in CR (20 after subsequent HSCT). Median duration of hematologic remission was not reached (supplemental Figure 3). Median OS was 36.5 months (95% CI, 19.8 months to not estimable), with a median follow-up of 30.0 months (Figure 3C). Among the entire study population of 116 patients, median OS was 36.5 months (95% CI, 19.2 months to not estimable; supplemental Figure 4).

Landmark analyses of RFS and OS by complete MRD response excluded 3 patients without MRD results ($n = 1$) or insufficient sensitivity of the assay ($n = 2$). The landmark of 45 days was used to represent the latest day of first MRD response assessment. Median RFS was 23.6 vs 5.7 months ($P = .002$) and median OS was 38.9 vs 12.5 months ($P = .002$) in patients with and without a complete MRD response in cycle 1, respectively (Table 2; Figure 3D). Median RFS was 13.9 months among patients in second or later CR who achieved a complete MRD response with blinatumomab; median RFS was not reached among patients in first CR who achieved a complete MRD response with blinatumomab (Figure 3E).

Seventy-four (67%) of 110 patients in the key secondary end point full analysis set underwent HSCT in continuous remission after blinatumomab: 55 in ongoing first CR and 19 in continuous second CR. Of the patients undergoing transplantation, 65% were age >35 years, and median age was 42.5 years (range, 18-67 years). Nine (25%) of 36 patients without HSCT or chemotherapy after blinatumomab remained in continuous CR, with a median follow-up of 24.0 months (range, 2.8-41.6 months), whereas 36 (49%) of 74 patients with HSCT remained in remission. Characteristics of patients who underwent postblinatumomab HSCT and a post hoc analysis of survival outcomes are summarized in supplemental Results B.

Adverse events

All 116 patients who started cycle 1 experienced at least 1 adverse event (supplemental Table 4). During cycles 2, 3, and 4,

Table 3. Summary of adverse events (full analysis set)

	All patients (N = 116)		
	Any grade	Grade 3	Grade 4
Any adverse event, n (%)	116 (100)	38 (33)	31 (27)
Non-neurologic adverse events, worst grade ≥ 3 occurring in $\geq 3\%$ of patients

Leukopenia	8 (7)	5 (4)	2 (2)
Anemia	7 (6)	4 (3)	1 (1)
ALT increased	7 (6)	2 (2)	4 (3)
Thrombocytopenia	6 (5)	2 (2)	3 (3)
AST increased	5 (4)	1 (1)	3 (3)
Any neurologic adverse event*	61 (53)	12 (10)	3 (3)
Neurologic events, worst grade ≥ 3			
Tremor	35 (30)	6 (5)	0 (0)
Aphasia	15 (13)	1 (1)	0 (0)
Dizziness	9 (8)	1 (1)	0 (0)
Confused state	6 (5)	1 (1)	0 (0)
Encephalopathy	6 (5)	3 (3)	2 (2)
Seizure	3 (3)	1 (1)	1 (1)
Disorientation	3 (3)	1 (1)	0 (0)
Depressed level of consciousness	1 (1)	1 (1)	0 (0)
Generalized tonic-clonic seizure	1 (1)	1 (1)	0 (0)

All adverse events regardless of causality that occurred during the treatment period plus 30 days. Thirty-six patients (31%) had treatment interruptions because of treatment-emergent adverse events, mainly as a result of neurologic events and flu-like symptoms. Those occurring in $\geq 2\%$ of patients included pyrexia (8%) and aphasia, encephalopathy, overdose, tremor, ALT increased, AST increased, and chills (3% each).

ALT, alanine aminotransferase; AST, aspartate aminotransferase.

*Among all patients. Multiple events may have occurred in some patients.

85%, 79%, and 75% of treated patients, respectively, experienced adverse events. Overall, 33% and 27% of patients had grade 3 and 4 adverse events, respectively (Table 3), including 20% and 18%, respectively, in cycle 1 and 11% each in cycle 2. Investigators considered grade 3 and 4 adverse events to be treatment related for 29% and 22% of patients, respectively. Four patients (3%) had cytokine release syndrome (grade 1, $n = 2$; grade 3, $n = 2$), all during cycle 1 (supplemental Table 4).

Sixty-one patients (53%) had neurologic events of any grade (Table 3), with decreasing incidence over cycles 1, 2, 3, and 4 of 47%, 24%, 15%, and 15%, respectively. Median duration from onset to resolution was 4 days (quartile 1, 2 days; quartile 3, 8 days). Twelve (10%) and 3 patients (3%) had grade 3 and 4 neurologic events, respectively, with 9%, 4%, 0%, and 0% reporting grade 3 and 4 events for cycles 1, 2, 3, and 4, respectively. Neurologic events resolved in 59 patients (97%) with any-grade events and in all patients with

grade 3/4 events. Most patients who had grade 3/4 neurologic events resumed blinatumomab treatment after the event resolved.

Two fatal adverse events were reported during the treatment period (both in cycle 1): atypical pneumonitis with H1N1 influenza (considered treatment related by the investigator) and subdural hemorrhage (considered unrelated to treatment by the investigator). Investigators reported 4 fatal adverse events after blinatumomab treatment, including 2 in patients who underwent HSCT after blinatumomab (multifocal central nervous system lesions and graft-versus-host disease at 124 and 136 days posttreatment, respectively) and 2 (disease progression and multiorgan failure at 154 and 359 days posttreatment, respectively) after subsequent relapse in patients not undergoing transplantation.

Discussion

To date, most investigational therapies in ALL have been evaluated in patients with overt relapse. This was the first international, multicenter study in ALL to combine MRD-based inclusion criteria with an MRD-based primary end point assessed per the central reference laboratory. This patient group was selected based on poor prognosis as a result of a high relapse rate with continued chemotherapy, indicating resistance to chemotherapy. A targeted therapy with an alternative mechanism of action administered before overt relapse may improve the outcome in these patients.

The results confirm and extend those of the pilot study of blinatumomab in MRD⁺ ALL, in which 80% of patients achieved an MRD response.^{21,22} However, in contrast to the pilot study, this study enrolled patients with MRD $\geq 10^{-3}$ (vs $\geq 10^{-4}$) and included patients in second or later CR, both indicators of increased risk. Nevertheless, across all groups evaluated, complete MRD response rates were high, and no demographic/clinical characteristics were associated with MRD response after 1 cycle. In relapsed/refractory ALL, the only baseline feature that was predictive of response to blinatumomab was blast percentage, with a 73% composite CR or CR with partial hematologic recovery rate in patients with <50% blasts in bone marrow.²⁴ This finding and the high response rates in MRD⁺ patients support the hypothesis that targeted single-drug immunotherapy has impressive antileukemic activity and that lower leukemia burden is a favorable prerequisite for this treatment principle.

Previous studies evaluating outcomes in adult patients with MRD⁺ ALL after conventional chemotherapy showed that MRD⁺ status was associated with shorter OS and RFS,^{5-7,16,25} and higher MRD burden was associated with shorter duration of hematologic remission and poorer outcomes despite continued chemotherapy.⁴ In this study, landmark analyses showed that achieving a complete MRD response was associated with prolonged OS and RFS compared with not achieving an MRD response, demonstrating a direct patient benefit for the immunotherapeutic conversion of MRD⁺ to MRD⁻ disease. Although MRD response rates were high in patients treated in second or third CR, RFS, OS, and duration of hematologic remission were inferior compared with patients treated in first CR. MRD response may have different implications in relapsed/refractory ALL, presumably due to genetic

instability and selection of more aggressive subclones, which are correlated to higher incidences of escape and resistance mechanisms.²⁶ Thus, treatment with blinatumomab in MRD⁺ disease during an ongoing first CR may be beneficial.

In contrast to stepwise dosing of blinatumomab to prevent cytokine release syndrome in the relapsed/refractory setting (9 μg per day for 1 week followed by 28 μg per day for 3 weeks in cycle 1),²⁴ we used a fixed blinatumomab dose of 15 $\mu\text{g}/\text{m}^2$ per day \times 28 days per cycle, corresponding to the fixed target dose of 28 μg per day for relapsed/refractory ALL. Despite implementation of a higher starting dose in this study, cytopenias, including those of grade 3/4, were less frequent compared with previous blinatumomab studies in relapsed/refractory ALL.^{18,22,24} The incidence of adverse events (including neurologic events) was greatest during cycle 1 and decreased over subsequent cycles. Neurologic events were mostly grade 1/2 and included tremor, aphasia, dizziness, encephalopathy, and seizure, with grade 1/2 tremor and aphasia occurring more frequently than in relapsed/refractory ALL.^{18,24} For those patients with adverse events leading to treatment interruptions, most events resolved rapidly after stopping blinatumomab, which has a serum half-life of ~ 2 hours. Most patients who had grade 3/4 neurologic events resumed blinatumomab treatment after the event resolved. Similar neurologic events have been observed with other CD19-directed therapies,²⁷⁻²⁹ in other T cell-activating studies,³⁰ and in blinatumomab studies in relapsed/refractory ALL and non-Hodgkin lymphoma.^{18,22,24} The pathogenesis of neurologic events is poorly understood and does not seem to be correlated to tumor burden, because rates of grade 3/4 neurologic events were similar for blinatumomab in relapsed/refractory ALL.²⁴ In the MRD setting, adverse events associated with cytokine release syndrome were observed infrequently ($n = 4$), and no deaths were related to neurologic events or cytokine release syndrome.

A median OS of 36.5 months, and an equivalent estimate for patients treated in first CR in this study, compares favorably to that in published data for MRD-positive ALL⁵ and relapsed/refractory ALL.²⁴ In this study, a median RFS of 18.9 months without censoring for HSCT was substantially greater than the median time to hematologic relapse of 7.6 months previously reported for patients in first CR with MRD $> 10^{-4}$ who did not undergo HSCT,⁵ suggesting that blinatumomab has the potential to improve the outcome of patients with chemotherapy-resistant disease. HSCT rates of 47% to 66% among patients with B-cell precursor ALL with MRD after standard frontline therapy have led to prolonged RFS.^{5,11} On the basis of these results, investigators offered HSCT in 67% of the patients in this study in remission after blinatumomab, because this became standard practice for MRD-positive patients in the countries participating in the trial. Because of changing practices, the proportion of patients undergoing HSCT was higher than expected. HSCT was also offered to older patients (65% age > 35 years), and 34% of the transplantations used mismatched donors. This broad indication for HSCT may have contributed to transplantation-related mortality; nevertheless, mortality is in line with reports of HSCT in standard of care ranging between 20% to 30%.³¹⁻³⁵ The proportion of patients not undergoing transplantation was small, and the study was neither planned nor powered to assess the impact of HSCT after blinatumomab treatment.

Nevertheless, a number of patients with a complete MRD response remained in long-term remission without subsequent HSCT, which confirms the experience of the pilot study with long-term survivors without subsequent HSCT.^{21,22} This observation might be of relevance for the development of future treatment strategies, particularly for less fit and elderly patients. Additional studies need to determine the role of HSCT in this setting, particularly regarding indications for HSCT.

Treatment of patients with persistent chemotherapy-resistant disease after conventional treatment remains a major challenge in the management of pediatric and adult ALL, with high relapse rates during continued chemotherapy and even after subsequent HSCT. Among patients with chemotherapy-resistant MRD, targeted immunotherapy with blinatumomab resulted in a substantial molecular response rate and improved long-term outcomes among responders compared with nonresponders. Our results suggest that targeted treatment in early stages of MRD is a viable therapeutic strategy for patients with B-cell precursor ALL and that it should also be evaluated in other hematologic malignancies.^{36,37}
