## Key Points

- Selective advantage induced by clonal hematopoiesis-associated mutation in *Dnmt3a* is specific to the HSC compartment.
- *Npm1* mutation alters chromatin accessibility in a cell-context and *Dnmt3a* mutation-dependent manner.

In adult acute myeloid leukemia (AML), the acquisition of driver somatic mutations may be preceded by a benign state termed clonal hematopoiesis (CH). To develop therapeutic strategies to prevent leukemia development from CH, it is important to understand the mechanisms by which CH-driving and AML-driving mutations cooperate. Here, we use mice with inducible mutant alleles common in human CH (*DNMT3A*<sup>R882</sup>; mouse *Dnmt3a*<sup>R878H</sup>) and AML (*NPM1*<sup>cA</sup>; mouse *Npm1*<sup>cA</sup>). We find that *Dnmt3a*<sup>R878H/+</sup> hematopoietic stem cells (HSCs), but not multipotent progenitor cell (MPP) subsets, have reduced cytokine expression and proinflammatory transcriptional signatures and a functional competitive advantage over their wild-type counterparts. *Dnmt3a*<sup>R878H/+</sup> HSCs are the most potent cell type transformed by *Npm1*<sup>cA</sup>, generating myeloid malignancies in which few additional cooperating somatic mutation events were detected. At a molecular level, *Npm1*<sup>cA</sup>, in cooperation with *Dnmt3a*<sup>R878H</sup>, acutely increased the accessibility of a distinct set of promoters in HSCs compared with MPP cells. These promoters were enriched for cell cycling, PI3K/AKT/mTOR signaling, stem cell signatures, and targets of transcription factors, including NFAT and the chromatin binding factor HMGB1, which have been implicated in human AML. These results demonstrate cooperativity between preexisting *Dnmt3a*<sup>R878H</sup> and *Npm1*<sup>cA</sup> at the chromatin level, where specific loci altered in accessibility by *Npm1*<sup>cA</sup> are dependent on cell context as well as *Dnmt3a* mutation status. These findings have implications for biological understanding and therapeutic intervention in the transformation from CH to AML.

## Introduction

Recurrent somatic mutations originally identified in de novo adult acute myeloid leukemia (AML), including a missense mutation in the DNA methyltransferase *DNMT3A* (*DNMT3A*<sup>R882H/C</sup>),<sup>1</sup> have been subsequently found in the benign state of aging-associated clonal hematopoiesis (CH/CHIP/ARCH).<sup>2-4</sup> While CH has been reported to confer a ~10-fold increased risk of development of hematologic malignancy,<sup>2,3,5</sup> most individuals with CH will not develop AML. Thus, the predictive power of CH in assessing

risk for hematologic malignancy is low. To develop better risk stratification and potentially new therapeutic approaches to prevent or intercept the development of AML, we need to understand the context in which and mechanisms by which CH can be transformed into AML.

Mutations in nucleophosmin (*NPM1*) are well documented as transformation events in de novo AML.<sup>6</sup> The cell of origin giving rise to *NPM1*-mutant AML has long been a matter of debate. *NPM1* mutations in AML samples can be found in multiple pools of stem and progenitor-like cells defined by CD34<sup>+</sup> CD38<sup>-</sup> or CD34<sup>-</sup> CD38<sup>+</sup> immunophenotypes, and these variably propagate disease in xenotransplant models.<sup>7,8</sup> Examining the normal HSC compartment within *NPM1*-mutant AML patients has shown that HSCs occasionally<sup>9</sup> but not always<sup>10</sup> harbor coincident *NPM1* mutations present in AML blasts. Taken together, previous studies suggest that there is not a single uniform cell type-of-origin for *NPM1*-mutant AML. However, inherent complexity and heterogeneity in human AML patient samples present a barrier to prospectively dissecting the mechanisms that dictate cell of origin.

Current proposed models of *DNMT3A*-mutant CH and progression to *DNMT3A*;*NPM1*-mutant AML posit that initiating *DNMT3A* mutations occur in an HSC and result in the generation of an expanded pool of HSCs and downstream progenitors within which *NPM1* mutations are acquired and drive progression to AML.<sup>10</sup> Here, we take advantage of our recently developed, orthogonally inducible murine models of *DNMT3A*<sup>R882H</sup> (murine *Dnmt3a*<sup>R878H/+</sup>) and *NPM1*<sup>c</sup> (murine *Npm1*<sup>cA/+</sup>)<sup>11</sup> to prospectively examine cell of origin in a controlled model organism system.

## Methods

### Animals

C57BL/6J (000664), B6.SJL-*Ptprca*<sup>a</sup>*Pepec*<sup>b</sup>/BoyJ ("CD45.1") (002014), *Dnmt3a*<sup>fl-R878H/+</sup> (032289), *Mx1-Cre* (003556), *Npm1*<sup>fl-cA/+</sup> (033164), and *Rosa26*<sup>FloER</sup> (018906) mice were bred within The Jackson Laboratory (JAX). CD45.1/CD45.2 mice were F1 progeny of a C57BL/6J × CD45.1 cross. For *Mx1-Cre* induction, mice received 15 mg/kg plpC (InvivoGen) by intraperitoneal injection every other day (5 times total). For FloER induction, mice received 125 mg/kg tamoxifen by oral gavage once daily (3 × total). The JAX animal care and use committee approved all experiments.

### Primary cell isolation and hematopoietic stem/progenitor cell phenotyping

Bone marrow (BM) mononuclear cells from femurs, tibiae, and iliac crests were isolated by Ficol-Paque (GE Healthcare) and stained with fluorochrome-conjugated antibodies from eBioscience, BD Biosciences, or BioLegend: CD45.1 (clone A20), CD45.2 (clone 104), c-Kit (clone 2B8), Sca-1 (clone 108129), CD150 (clone TC15-12F12.2), CD48 (clone HM48-1), FLT3 (Clone A2F10), CD34 (clone RAM34), FcγR (clone 2.4G2), mature lineage (Lin) marker mix (B220 [clone RA3-6B2], CD11b [clone M1/70], CD4 [clone RM4-5], CD8a [clone 53-6.7], Ter-119 [clone TER-119], Gr-1 [clone RB6-8C5]), and the viability stain propidium iodide. Stained cells were sorted using a FACS Aria, or analyzed on a LSR II or Symphony (BD) using the following profiles: HSC (Lin<sup>-</sup> Sca-1<sup>+</sup> c-Kit<sup>+</sup> Flt3<sup>-</sup> CD150<sup>+</sup> CD48<sup>-</sup>), MPP (Lin<sup>-</sup> Sca-1<sup>+</sup> c-Kit<sup>+</sup> Flt3<sup>-</sup> CD150<sup>-</sup> CD48<sup>-</sup>), MPP<sup>G/M</sup> (Lin<sup>-</sup> Sca-1<sup>+</sup> c-Kit<sup>+</sup> Flt3<sup>-</sup> CD150<sup>-</sup>

CD48<sup>+</sup>), MPP<sup>ly</sup> (Lin<sup>-</sup> Sca-1<sup>+</sup> c-Kit<sup>+</sup> Flt3<sup>+</sup> CD48<sup>+</sup>), GMP (Lin<sup>-</sup> Sca-1<sup>-</sup> c-Kit<sup>+</sup> CD34<sup>+</sup> FcγR<sup>hi</sup>), and MEP (Lin<sup>-</sup> Sca-1<sup>-</sup> c-Kit<sup>+</sup> CD34<sup>-</sup> FcγR<sup>lo</sup>).

### 4'-hydroxytamoxifen (4-OHT) dose response

HSC and GMP populations were isolated from *Npm1*<sup>fl-cA/+</sup>; *Rosa26*<sup>FloER</sup> or control *Npm1*<sup>+/+</sup>; *Rosa26*<sup>FloER</sup> mice. For cell viability, 10 000 *Npm1*<sup>+/+</sup> GMPs were plated with 0, 10, or 20 μM 4-OHT (Sigma) in Iscove's Modified Dulbecco's Medium (IMDM) plus 100 ng/mL SCF, 100 ng/mL interleukin-6 (IL-6), and 100 ng/mL IL-3 in IMDM + 10% fetal bovine serum (FBS). After 2 hours or 24 hours, the full contents of each well were harvested and counted with trypan blue viability stain. For allele recombination, 1000 *Npm1*<sup>fl-cA/+</sup> HSCs were plated with 10 or 20 μM 4-OHT in StemSpan (StemCell Technologies) plus 100 ng/mL SCF, 200 ng/mL TPO, 100 ng/mL IGF2, and 100 ng/mL FGF. In parallel, 10 000 *Npm1*<sup>fl-cA/+</sup> GMPs were plated with 10 or 20 μM 4-OHT in the media described above. After 2 hours or 24 hours, DNA extraction was performed using a DNeasy Blood & Tissue Kit (Qiagen) and *Npm1* allele recombination polymerase chain reaction (PCR) as previously described.<sup>11</sup>

### In vivo transplantation

For competitive transplant, 200 HSCs, 200 MPP cells, or 400 MPP<sup>G/M</sup> cells were sorted from *Dnmt3a*<sup>R878H/+</sup>; *Mx1-Cre* and CD45.1/CD45.2 mice, pooled at a 1:1 ratio, and IV-injected into recipient CD45.1 mice after 1000 rads irradiation (split dose, 3 hours apart). For secondary transplant, 2 × 10<sup>6</sup> BM cells from primary recipients were IV-injected into individual CD45.1 recipient mice after 1200 rads irradiation (split dose). For noncompetitive transplant, 1000 HSCs, 5000 MPP<sup>G/M</sup> cells, 5000 MEP cells, and 7000 to 10 000 GMP cells were sorted into separate wells containing 10 μM 4-OHT. For HSC, MPP<sup>G/M</sup>, and MEP cells, culture media contained 100 ng/mL SCF, 200 ng/mL TPO, 100 ng/mL IGF2, and 100 ng/mL FGF in StemSpan. For GMP cells, culture media contained 100 ng/mL SCF, 100 ng/mL IL-6, and 100 ng/mL IL-3 in IMDM + 10% FBS. After 24 hours, the contents of each well were IV injected into recipient CD45.1 mice after 1000 rads irradiation (split dose). In all transplants, peripheral blood (PB) samples were assessed by flow cytometry using a cocktail of CD45.1, CD45.2, B220, CD3e (clone 145-2C11), Ly6g (clone 1A8), and Ly6c (clone HK1.4) antibodies. At the end of the transplant, BM samples were assessed using the antibody cocktail described above for hematopoietic stem/progenitor cells.

### Analysis of moribund mice

Mice with declining health status were sacrificed, and PB, spleen, liver, and BM were harvested. Complete blood counts were obtained from PB, and blood smears stained with Wright's Giemsa. Cytospin preparations of whole BM mononuclear cells were stained with May-Grunwald Giemsa stain. Liver and spleen samples were fixed for 24 hours in 10% buffered formalin phosphate, embedded in paraffin, and sections stained with H&E. Images were captured on a Nikon Eclipse Ci upright microscope with SPOT imaging software (v.5.6). Histological assessment and diagnosis were performed independently by 2 individuals in a blinded manner.

## RNA sequencing (RNA-Seq)

Two thousand HSCs, MPP, MPP<sup>G/M</sup>, and MPP<sup>L<sub>y</sub></sup> cells were fluorescence-activated cell sorting (FACS) sorted from independent biological replicate *Dnmt3a*<sup>fl-R878H/+</sup>; *Mx1-Cre* or *Dnmt3a*<sup>+/+</sup>; *Mx1-Cre* mice directly into RLT buffer (Qiagen) and flash frozen. Total RNA was isolated using the RNAeasy Micro Kit (Qiagen) and assessed using a Nanodrop 2000 spectrophotometer (Thermo Scientific) and RNA 6000 Pico LabChip assay (Agilent Technologies). Libraries were prepared using the Ovation RNA-seq System V2 (NuGen) and Hyper Prep Kit (Kapa Biosystems). Library quality and concentration were evaluated using D5000 ScreenTape assay (Agilent) and quantitative PCR (Kapa Biosystems). Libraries were pooled and sequenced 75 bp single end on the NextSeq (Illumina) using NextSeq High Output Kit v2 reagents at a sequencing depth of >30 million reads per sample. Trimmed alignment files were processed using RNA-Seq by Expectation Maximization (RSEM) (v1.2.12). Alignment was completed using Bowtie 2 (v2.2.0). Expected read counts per gene produced by RSEM were rounded to integer values, filtered to include only genes that have at least 2 samples within a sample group having a cpm >1, and were passed to edgeR (v3.14.0) for differential expression analysis. The generalized linear model likelihood ratio test was used for differential expression in pairwise comparisons between sample groups which produced exact *P* values per test. The Benjamini and Hochberg's algorithm (*P* value adjustment) was used to control the false discovery rate (FDR). Features with FDR-adjusted *P* value < .05 were declared significantly differentially expressed.

## Assay for transposase-accessible chromatin with high-throughput sequencing (ATAC-Seq)

HSCs and MPP<sup>G/M</sup> cells were sorted and transposed for ATAC library preparation adapted from Buenrostro and colleagues.<sup>12</sup> Briefly, nuclei were prepared, DNA was transposed and purified, followed by PCR amplification. ATAC-seq libraries were evaluated for quality and concentration using the High Sensitivity DNA Assay (Agilent Technologies) and KAPA Library Quantification Kit (Roche Sequencing and Life Science), respectively, according to the manufacturers' instructions. Libraries were pooled and sequenced 75 bp paired-end on the HiSeq 4000 (Illumina) using HiSeq 3000/4000 SBS Kit reagents (Illumina). FASTQ files per each sample were initially analyzed with easy-to-use systematic pipeline for ATAC-seq data analysis (esATAC) v1.12.0 under R v3.6.0 using the mm10 reference genome. Read counts were extracted from peak call and alignment data using DiffBind v2.12.0. edgeR v3.26.4 was used to calculate differential binding of the trimmed mean of the M-values—normalized counts. If a region did not have at least 1 sample with cpm >1, the region was omitted from the pairwise comparison's differential analysis. The negative binomial conditional common likelihood was maximized to estimate a common dispersion value across all features/regions. Exact tests were used to elucidate statistical differences between the 2 sample groups of negative binomially distributed counts producing *P* values per test. The Benjamini and Hochberg's algorithm (*P* value adjustment) was used to control the FDR. Features with an FDR-adjusted *P* value < .05 were declared statistically significant. Differential binding results were annotated using HOMER v4.10.

## M-impact

Genomic DNA underwent targeted capture and deep sequencing within the Memorial Sloan Kettering Cancer Center (MSKCC) Integrated Genomics Operation Core using the MSK M\_IMPACT (mouse Integrated Mutation Profiling of Actionable Cancer Targets) assay. Mouse genomic DNA was used for library construction with molecular barcoding of each sample before capture and sequencing. Pooled libraries were sequenced paired-end 125 bp reads on an Illumina HiSeq with 500× coverage. Sequencing analysis was performed by the MSKCC Bioinformatics Core. FASTQ files were mapped to the mouse reference genome mm10 using Burrows-Wheeler Aligner v0.7.12. The resulting files were sorted, grouped, and PCR duplicates identified by MarkDuplicates in PICARD Tools (v1.124). BAM files were processed through GATK (genomic analysis toolkit) toolkit (v3.2) to perform variant calling in tumor-vs-normal paired mode. Variant allele frequency was determined by calculating the fraction of variant reads for a specific count out of the total reads at that location.

## Statistical analysis

Statistical analysis was performed by unpaired Student *t* test or two-way ANOVA followed by uncorrected Fisher's least significant difference. Statistics for survival curves were performed by log-rank Mantel-Cox test. All statistical tests were performed using Prism 8 software (GraphPad).

## Results

### *Dnmt3a*<sup>R878H/+</sup> preserves molecular self-renewal programs selectively in HSCs

First, we asked which cell type(s) within the adult hematopoietic stem and progenitor cell compartment would incur transcriptional alterations due to *Dnmt3a*<sup>R878H</sup> expression. We administered polyI:C to induce *Mx-Cre* recombinase in control or *Dnmt3a*<sup>fl-R878H/+</sup> mice, and 6 weeks later, prospectively isolated HSCs, MPP, MPP<sup>G/M</sup>, and MPP<sup>L<sub>y</sub></sup> cells for RNA-seq, based on a recently established consensus cell surface phenotyping scheme for MPP isolation<sup>13</sup> (Figure 1A). All 4 of these populations were isolated from the same individual mice (*n* = 3 to 4 biological replicates). We validated the enrichment of these cell populations by verifying transcript expression of key cell surface markers used for prospective isolation, such as enrichment of *Slamf1* (CD150) and *Cttnal1* (α-catulin) in HSCs, depletion of *Cd34* (CD34) in MPPs, enrichment of *Cd48* in MPP<sup>G/M</sup> and MPP<sup>L<sub>y</sub></sup> cells, and enrichment of *Fit3* in MPP<sup>L<sub>y</sub></sup> cells (supplemental Figure 1A). To provide greater insight into the differences between *Dnmt3a*<sup>R878H/+</sup> and *Mx-Cre* control HSCs, we incorporated a previously generated dataset of HSCs from non-polyI:C-treated, wild-type young C57BL/6 mice.<sup>14</sup> Using principal component analysis, we found that *Dnmt3a*<sup>R878H/+</sup> HSCs cluster in a position spatially proximal to wild-type HSCs, whereas the *Mx-Cre* control HSCs clustered distally to these groups (Figure 1B). In addition, we observed highly similar expression patterns between *Dnmt3a*<sup>R878H/+</sup> and *Mx-Cre* control MPP, MPP<sup>G/M</sup>, and MPP<sup>L<sub>y</sub></sup> cell types. We identified 412 significantly differentially expressed genes in *Dnmt3a*<sup>R878H/+</sup> vs *Mx-Cre* control HSCs, the majority of which were more highly expressed in *Mx-Cre* controls (Figure 1C). These included myeloid differentiation genes such as *Elane* and *Mpo*, which were most highly expressed in the MPP<sup>G/M</sup> compartment (supplemental Figure 1B) and exhibited increased expression in *Mx-Cre* control vs wild-type HSCs, but not in

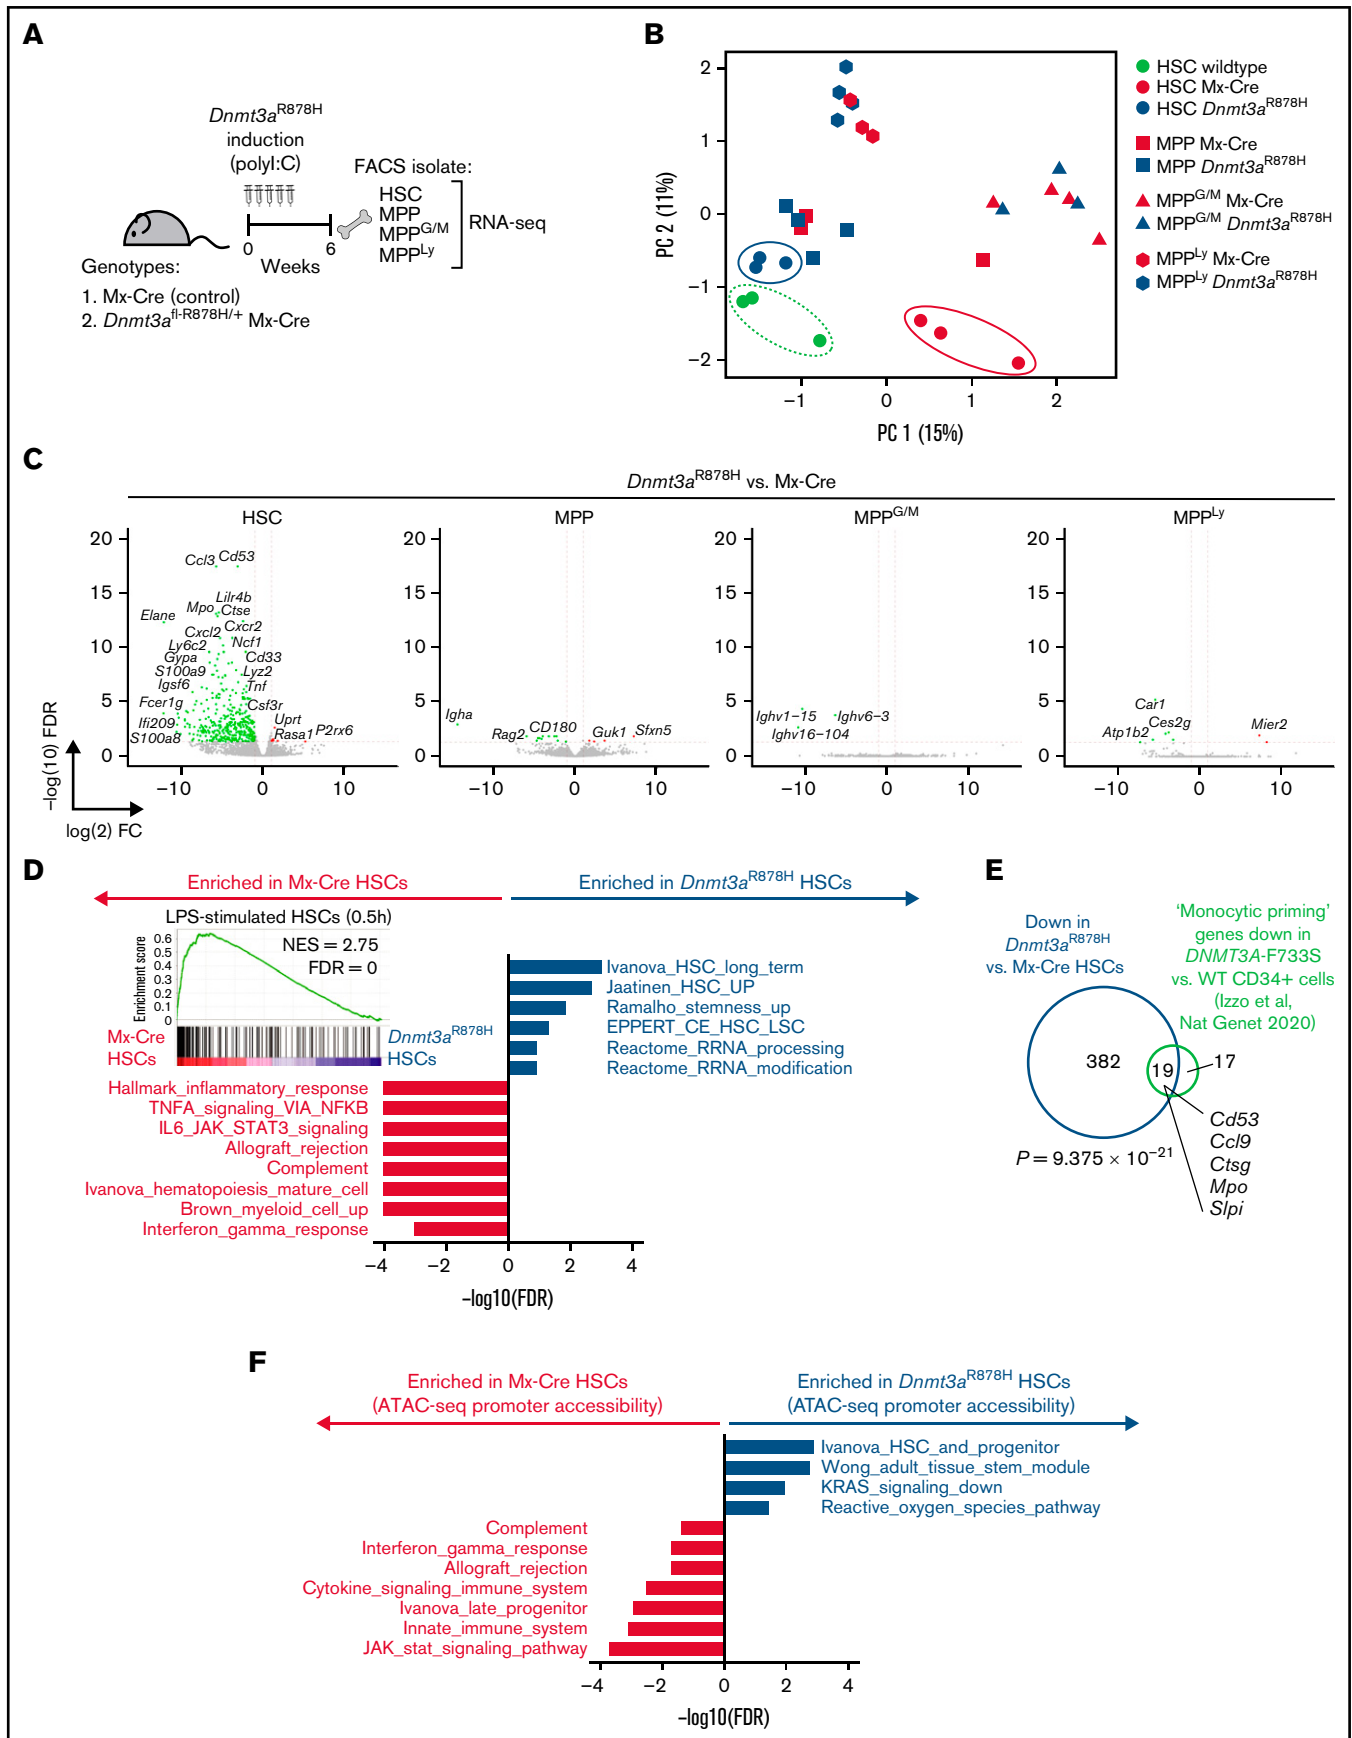

Figure 1.

*Dnmt3a*<sup>R878H/+</sup> HSCs (supplemental Figure 1C). In addition, *Cd53* was expressed at a similar level across the stem and progenitor cell subsets but was specifically increased in *Mx-Cre* control vs wild-type HSCs (supplemental Figure 1B,C). We observed that *Prg2*, which was recently shown by Katherine King's group to be resistant to interferon induction in *Dnmt3a*<sup>-/-</sup> HSCs using a chronic mycobacterial infection model,<sup>15</sup> was specifically increased in *Mx-Cre* control vs wild-type HSCs but not in *Dnmt3a*<sup>R878H/+</sup> HSCs (supplemental Figure 1B-C).

Using gene set enrichment analysis of *Mx-Cre* control vs *Dnmt3a*<sup>R878H/+</sup> HSCs, we found that control HSCs were enriched for myeloid differentiation, cytokine signaling, and innate immune response signatures, whereas *Dnmt3a*<sup>R878H/+</sup> HSCs were enriched for stem cell and self-renewal-associated signatures (Figure 1D). Furthermore, we found that a published LPS-treated HSC gene signature<sup>16</sup> was enriched in control vs *Dnmt3a*<sup>R878H/+</sup> HSCs (Figure 1D, inset). This finding is consistent with the observation that *Dnmt3a*<sup>-/-</sup> HSCs have reduced transcriptional response to interferon stimulation and that polyI:C treatment provides an additional selective pressure favoring expansion of *Dnmt3a*<sup>-/-</sup> HSCs.<sup>15</sup> In addition, we compared our differentially expressed gene list to a "monocytic priming" gene signature identified as a decreased expression in human *DNMT3A*-R773S vs wild-type CD34<sup>+</sup> hematopoietic stem and progenitor cells in a *DNMT3A*-mutant CH carrier (Izzo and colleagues, Nat Genet 2020). We found a significant overlap between these gene sets ( $P = 9.375 \times 10^{-21}$  by hypergeometric test) (Figure 1E), supporting the relevance of transcriptional alterations in our model to human *DNMT3A*-mutant CH. Together, our data suggest that (1) very few genes are differentially expressed as an immediate-early consequence of *Dnmt3a*<sup>R878H</sup> in MPP, MPP<sup>G/M</sup>, and MPP4<sup>Ly</sup> cells, and (2) *Dnmt3a*<sup>R878H</sup> HSCs have reduced transcriptional alterations in response to polyI:C treatment and/or *Mx-Cre* expression compared with control HSCs.

To further refine the molecular mechanisms driving these transcriptional differences in *Dnmt3a*<sup>R878H/+</sup> HSCs, we performed ATAC-seq on *Mx-Cre* control and *Dnmt3a*<sup>R878H/+</sup> HSCs that had been induced by polyI:C at 8 weeks before harvest (detailed schematic shown in Figure 4A). Focusing on promoter accessibility changes in control vs *Dnmt3a*<sup>R878H/+</sup> HSCs, we found similar enrichment to our transcriptional pathway analysis in Figure 1D, including enrichment of cytokine signaling, innate immune system, and JAK/STAT signaling signatures in promoters with increased accessibility in control HSCs, whereas promoters with increased accessibility in *Dnmt3a*<sup>R878H/+</sup> HSCs were enriched in stem cell and self-renewal-associated signatures (Figure 1F). Our data support that

changes in promoter accessibility caused by the *Dnmt3a*<sup>R878H</sup> mutation are aligned at a pathway level with transcriptional patterns specific to *Dnmt3a*<sup>R878H/+</sup> HSCs.

### ***Dnmt3a*<sup>R878H/+</sup> confers a sustained functional advantage, specifically in HSCs**

We next tested the functional consequences of *Dnmt3a*<sup>R878H</sup> in subsets of hematopoietic stem and progenitor cells by competing them against their wild-type counterparts in vivo. We transplanted purified polyI:C-treated *Dnmt3a*<sup>R878H/+</sup> HSCs, MPP, and MPP<sup>G/M</sup> cells in a 1:1 ratio with wild-type HSCs, MPP, or MPP<sup>G/M</sup> cells into lethally irradiated recipients (Figure 2A). In the PB of primary transplant recipients, we observed decreased engraftment of *Dnmt3a*<sup>R878H/+</sup> HSCs and MPP cells compared with their wild-type counterparts and no difference in engraftment of *Dnmt3a*<sup>R878H/+</sup> MPP<sup>G/M</sup> cells (Figure 2B; supplemental Figure 2A). However, at the end of the transplant period, we found that *Dnmt3a*<sup>R878H/+</sup> HSCs had higher engraftment of the BM compared with wild-type HSCs (Figure 2C). This was specific to HSCs, as transplanted *Dnmt3a*<sup>R878H/+</sup> MPP and MPP<sup>G/M</sup> cells did not have a selective advantage over their wild-type counterparts in the BM. To evaluate the self-renewal and stem cell function of *Dnmt3a*<sup>R878H/+</sup> HSCs, we performed secondary transplantation and found that *Dnmt3a*<sup>R878H/+</sup> HSCs sustained higher engraftment in secondary transplant recipients assessed both in the PB and BM compared with wild-type HSCs (Figure 2D-E; supplemental Figure 2B). This is consistent with previous reports that *Dnmt3a*<sup>-/-</sup> HSCs gain a selective advantage over wild-type HSCs by enhancing self-renewal at the expense of differentiation.<sup>17</sup> Our data demonstrate that *Dnmt3a*<sup>R878H/+</sup> provides a sustained selective advantage specific to HSCs.

### ***Dnmt3a*<sup>R878H/+</sup> HSCs are the most potent cell of origin transformed by *Npm1*<sup>c</sup> mutation**

In murine models, the *Npm1*<sup>c</sup> mutation has been found to be a leukemia-driving allele in part through conferring self-renewal capacity onto myeloid progenitor cell populations.<sup>18,19</sup> We next asked which stem or progenitor cell subsets with preexisting *Dnmt3a* mutation could be transformed by *Npm1*<sup>cA</sup>. To induce *Npm1*<sup>cA</sup> in a precise, cell context-specific manner, we isolated HSCs, MPP<sup>G/M</sup> cells, and 2 committed progenitor cell populations (megakaryocyte-erythroid progenitors [MEPs] and GMPs) from individual *Dnmt3a*<sup>R878H/+</sup> mice treated with 4-OHT over 24 hours ex vivo to activate the *Npm1* mutation, then transplanted cells back into individual recipient animals along with a radioprotective dose of BM support cells and followed until moribund (Figure 3A). We experimentally determined the dose and timing of 4-OHT to preserve cell viability (supplemental Figure 3A) while maximizing the recombination efficiency of the

**Figure 1 (continued) *Dnmt3a*<sup>R878H/+</sup> reduces proinflammatory transcriptional programs, specifically in HSCs.** (A) Experimental design. (B) Principal component analysis of RNA-seq data from *Dnmt3a*<sup>R878H/+</sup> and *Mx-Cre* control cell types as well as C57BL/6 HSCs ( $n = 3$  to 4 biological replicate mice per condition). (C) Volcano plots of differential gene expression in *Dnmt3a*<sup>R878H/+</sup> vs *Mx-Cre* control cell types. Significant differential expression (FDR < 0.05) is indicated by colored dots; green dots (left side of each plot) represent genes lower in expression in *Dnmt3a*<sup>R878H/+</sup> vs control cells, and red dots (right side of each plot) represent genes higher in expression in *Dnmt3a*<sup>R878H/+</sup> vs control cells. (D) Gene signatures significantly enriched in *Mx-Cre* control (gray) or *Dnmt3a*<sup>R878H/+</sup> (navy) HSCs. (inset) Enrichment of a lipopolysaccharide-stimulated HSC signature<sup>16</sup> in control vs *Dnmt3a*<sup>R878H/+</sup> HSCs. (E) Venn diagram of overlapping downregulated genes in mouse *Dnmt3a*<sup>R878H/+</sup> vs control HSCs with downregulated "Monocytic Priming" genes in human *DNMT3A*-F733S vs wild-type CD34<sup>+</sup> cells.<sup>41</sup>  $P$  value calculated using a hypergeometric test. (F) Gene signatures significantly enriched in accessible promoters of *Mx-Cre* control (gray) or *Dnmt3a*<sup>R878H/+</sup> (navy) HSCs.

*Npm1* allele (supplemental Figure 3B). These experiments were initiated from starting cell numbers that we routinely isolate from individual mice and are proportional to the abundance of these populations in the BM; 1000 HSCs ( $n = 5$ ), 5000 MPP<sup>G/M</sup> cells ( $n = 3$ ), 5000 MEP cells ( $n = 6$ ) and 7000 to 10 000 GMP cells ( $n = 5$ ). We found that mice receiving *Dnmt3a*<sup>R878H/+</sup>; *Npm1*<sup>CA</sup> HSCs had fully penetrant disease development and statistically shorter overall survival than mice receiving MEP or GMP cells (Figure 3B). Mice transplanted with MPP<sup>G/M</sup> cells had a disease penetrance and survival that appeared intermediate between HSCs and MEP/GMP cells, although due to the low number of animals in this group, this cannot be rigorously statistically evaluated. All moribund mice were diagnosed with either myelodysplasia (MDS), myeloproliferative disorder (MPD), or acute myeloid leukemia (AML) based on complete blood counts, spleen weight, and blinded histological assessment of blood, BM, liver, and spleen (Figure 3C). We did not detect trends in disease states associated with different cell types, although our study was not statistically powered to assess differences at this level. In independent experiments evaluating *Npm1*<sup>CA</sup> as a single mutation (supplemental Figure 3C), we found that mice receiving *Npm1*<sup>CA</sup>-mutant-only MPP<sup>G/M</sup> had fully penetrant disease development and statistically shorter overall survival compared with mice receiving HSC, MEP, or GMP cells (supplemental Figure 3D), and moribund mice developed a spectrum of MDS, mixed MDS/MPD, MPD, and AML phenotypes (supplemental Figure 3E). In independent experiments evaluating disease development in mice transplanted with *Dnmt3a*<sup>R878H/+</sup>-mutant-only whole BM (supplemental Figure 3F), we found only 1 in 5 recipients developed a mild MDS-like phenotype (supplemental Figure 3G,H).

Our previous work identified human AML-relevant cooperating mutations as being spontaneously accrued in our *Dnmt3a*<sup>R878H/+</sup>; *Npm1*<sup>CA</sup> model.<sup>11</sup> We performed targeted sequencing of *Dnmt3a*<sup>R878H/+</sup>; *Npm1*<sup>CA</sup> myeloid malignancies to evaluate whether cooperating somatic mutations were differentially accrued depending on cell of origin. We observed that the myeloid malignancy generated from *Dnmt3a*<sup>R878H/+</sup>; *Npm1*<sup>CA</sup> MEP cells had a greater number of cooperating somatic mutations than the malignancies generated from HSC and MPP<sup>G/M</sup> cells (Figure 3D). The only recurrent mutation identified was in the AML-associated allele *Cbl*<sup>20</sup> and this was only found in the context of disease initiated by MPP<sup>G/M</sup> or MEP cells. Together, our data support that within the pool of stem and progenitor cells in *Dnmt3a*<sup>R878H/+</sup> mice, initiation of *Npm1*<sup>CA</sup> in HSCs results in the most potent development of hematologic malignancy. Furthermore, our data suggest that increased genomic instability and accrual of a greater number of cooperating somatic mutations is not an underlying explanation for why *Dnmt3a*<sup>R878H/+</sup> HSCs were the cell type most potently transformed by *Npm1*<sup>CA</sup>.

### ***Npm1*<sup>CA</sup> causes distinct chromatin accessibility changes in *Dnmt3a*<sup>R878H/+</sup> HSCs**

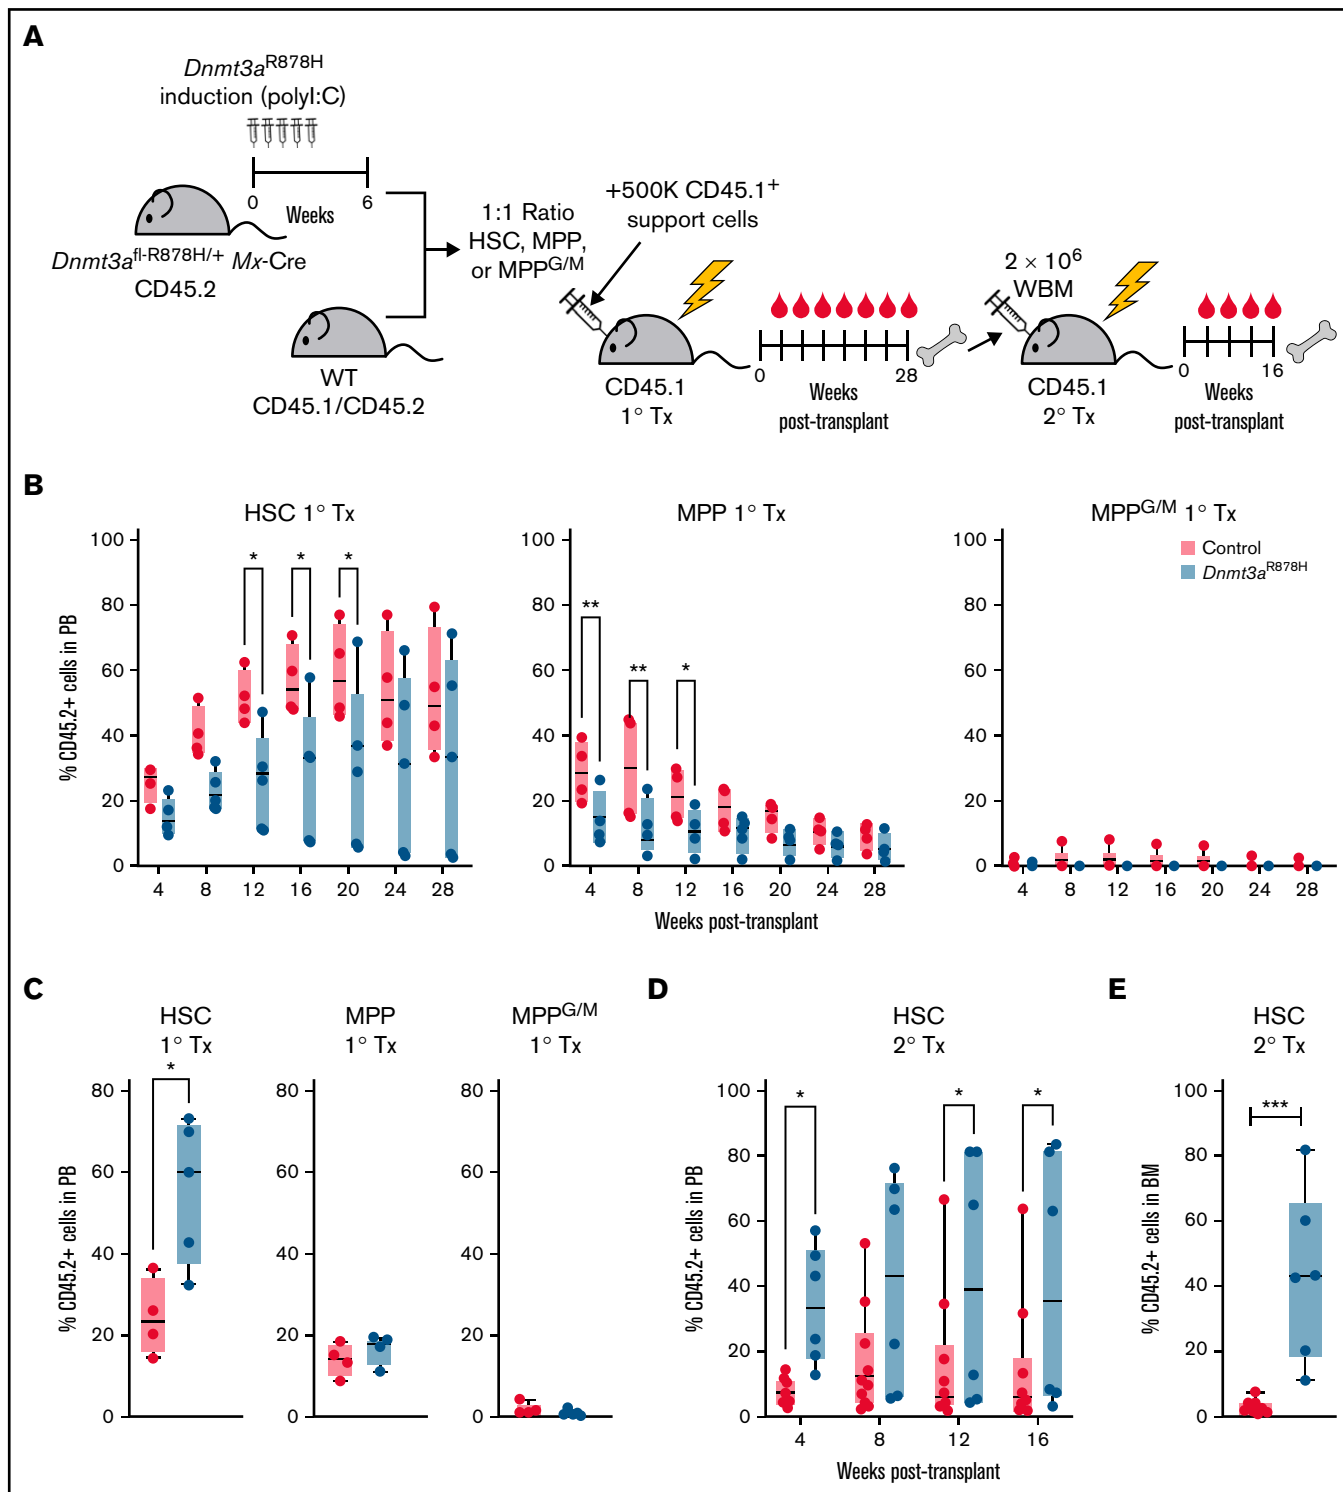

To interrogate molecular alterations induced by *Npm1*<sup>CA</sup> in *Dnmt3a*<sup>R878H/+</sup> HSCs, we assessed the chromatin landscape using ATAC-seq, following our previous observation that pathway enrichment was consistent among accessible promoter regions and transcriptional patterns in *Dnmt3a*<sup>R878H/+</sup> HSCs (Figure 1D,F). Control, *Npm1*<sup>flr-cA/+</sup>, *Dnmt3a*<sup>fl-R878H/+</sup>, or *Dnmt3a*<sup>fl-R878H/+</sup>; *Npm1*<sup>flr-cA/+</sup> BM were transplanted into lethally irradiated recipients (Figure 4A). At 4 weeks after transplant, all mice received poly(I:C) to induce

*Dnmt3a*<sup>R878H</sup>, followed 4 weeks later by tamoxifen to induce *Npm1*<sup>CA</sup>. At 4 weeks after tamoxifen, all mice were harvested, and donor-derived HSC and MPP<sup>G/M</sup> cells were isolated by FACS for ATAC-seq. Using principal component analysis of a cumulative set of the top differentially accessible promoter regions in HSCs and MPP<sup>G/M</sup> cells, we discovered that HSCs of different genotypes were better separated by accessible promoters than the MPP<sup>G/M</sup> populations (Figure 4B), suggesting that alterations in chromatin accessibility caused by these mutations are cell context-specific. To assess changes in promoter accessibility caused by *Npm1*<sup>CA</sup> on the background of a preexisting *Dnmt3a*<sup>R878H</sup> mutation, we compared *Dnmt3a*<sup>R878H/+</sup>; *Npm1*<sup>CA/+</sup> vs *Dnmt3a*<sup>R878H/+</sup> HSC and MPP<sup>G/M</sup> cells. We observed that HSCs had a greater number of promoters with increased accessibility than MPP<sup>G/M</sup> cells, and there was very little overlap between the cell types (Figure 4C). Conversely, MPP<sup>G/M</sup> cells had a larger number of promoters with decreased accessibility compared with HSCs, and there was also very little overlap between the cell types. Of note, several *Hox* genes (including *Hoxa9*) and *Meis1* were found to have increased promoter accessibility in *Dnmt3a*<sup>R878H/+</sup>; *Npm1*<sup>CA/+</sup> vs *Dnmt3a*<sup>R878H/+</sup> HSCs (supplemental Figure 4A), consistent with induction of these transcripts by *Npm1*<sup>c.19,21,22</sup>. In contrast, *Dnmt3a*<sup>R878H/+</sup>; *Npm1*<sup>CA/+</sup> MPP<sup>G/M</sup> cells only had a modest increase in expression of 1 *Hox* gene (*Hoxa10*). These results support that cell context can impact chromatin alterations induced by *Npm1*<sup>CA</sup> on a *Dnmt3a*<sup>R878H</sup> background.

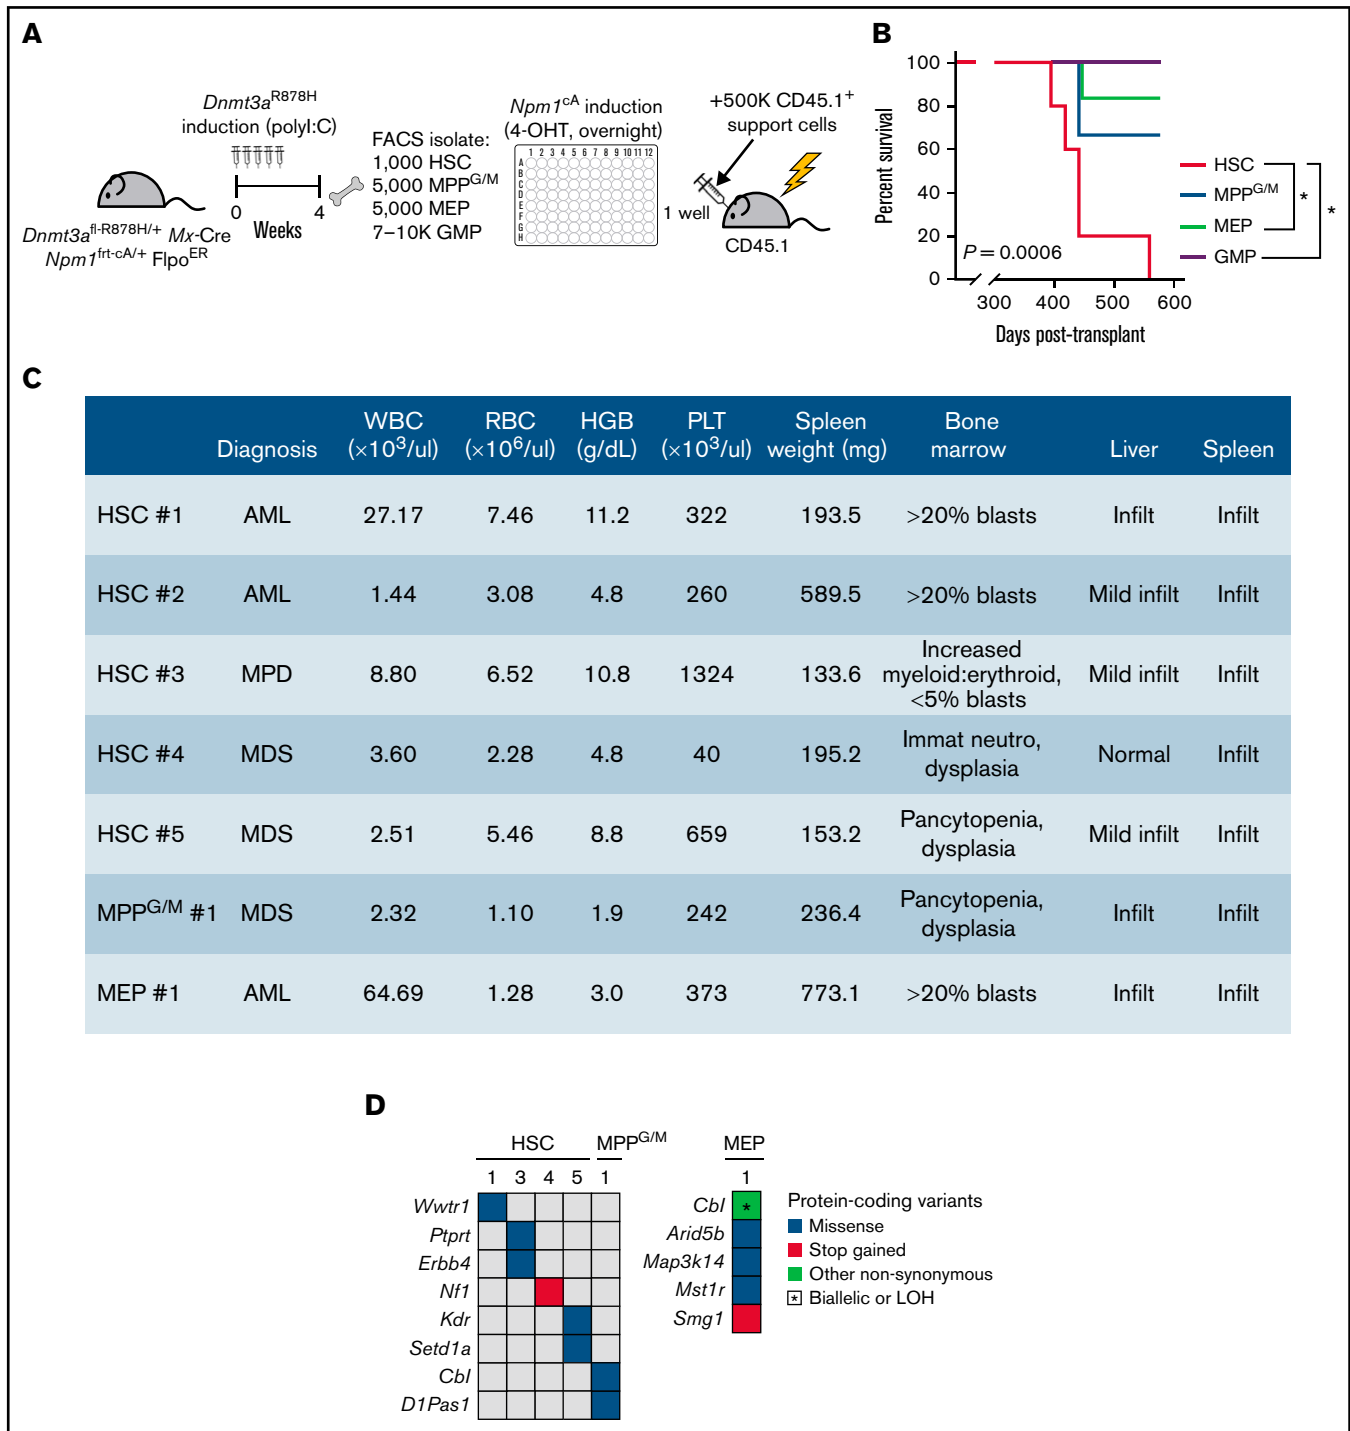

To gain further insight into the biological implications of altered promoter accessibility, we used pathway enrichment and transcription factor motif predictions from the molecular signatures database. *Dnmt3a*<sup>R878H/+</sup>; *Npm1*<sup>CA/+</sup> HSCs gained accessibility to promoters enriched in cell cycling, PI3K/Akt/mTOR signaling, and metabolic and stem cell pathways (Figure 4D), and were enriched in binding sites for transcription factors such as FOXP2,<sup>23</sup> NFAT,<sup>24</sup> MEF2,<sup>25</sup> and the chromatin binding factor HMGB1,<sup>26</sup> which have been implicated in human AML (Figure 4E). These were distinct from promoter accessibility gains, pathway, and transcription factor binding site enrichment in *Npm1*<sup>c</sup> HSCs without a preexisting *Dnmt3a* mutation (supplemental Figure 4C,D). With respect to reduced promoter accessibility in *Dnmt3a*<sup>R878H/+</sup>; *Npm1*<sup>CA/+</sup> cells, these regions were enriched in targets of the polycomb repressive complex PRC2 (Figure 4F) and binding sites for the tumor suppressor TFEB<sup>27</sup> (Figure 4G). Promoters with reduced accessibility in *Dnmt3a*<sup>R878H/+</sup>; *Npm1*<sup>CA/+</sup> cells were also enriched for a gene set downregulated in expression in human *NPM1*-mutant AML,<sup>28</sup> supporting human relevance of chromatin accessibility changes observed in our mouse model. Taken together, our results suggest that unique chromatin changes are induced by *Npm1*<sup>CA</sup> in the context of *Dnmt3a*<sup>R878H/+</sup> HSCs, which are correlated with *Dnmt3a*<sup>R878H/+</sup> HSCs being the cell type most potently transformed by *Npm1*<sup>CA</sup>, and that activation of HSC cycling and PI3K/Akt/mTOR signaling may be early preleukemic mechanisms.

## **Discussion**

While much of the literature describing functional data in mouse models of *DNMT3A*-mutant CH have used *Dnmt3a* conditional knockout mice,<sup>15,17,29,30</sup> human AML is largely comprised of monoallelic somatic *DNMT3A* mutations, with R882H being the

**Figure 2. *Dnmt3a*<sup>R878H/+</sup> confers a fitness advantage selectively in HSCs.** (A) Experimental design. most prevalent hotspot mutation.<sup>31,32</sup> Biochemically, partial loss-of-function,<sup>33,34</sup> dominant-negative,<sup>35,36</sup> and gain-of-function effects<sup>37</sup> on DNA methylation have all been associated with *DNMT3A*<sup>R882</sup> mutation. Furthermore, Russler-Germain and colleagues have demonstrated differences in DNA hypomethylation

patterns between *DNMT3A*<sup>R882</sup>-mutant and non-R882 *DNMT3A*-mutant AML patient samples,<sup>36</sup> suggesting that *DNMT3A*<sup>R882</sup> is not simply a loss-of-function allele. Thus, as a foundation for our study, it was important to evaluate whether our *Dnmt3a*<sup>R878H</sup> knock-in allele would induce functional and

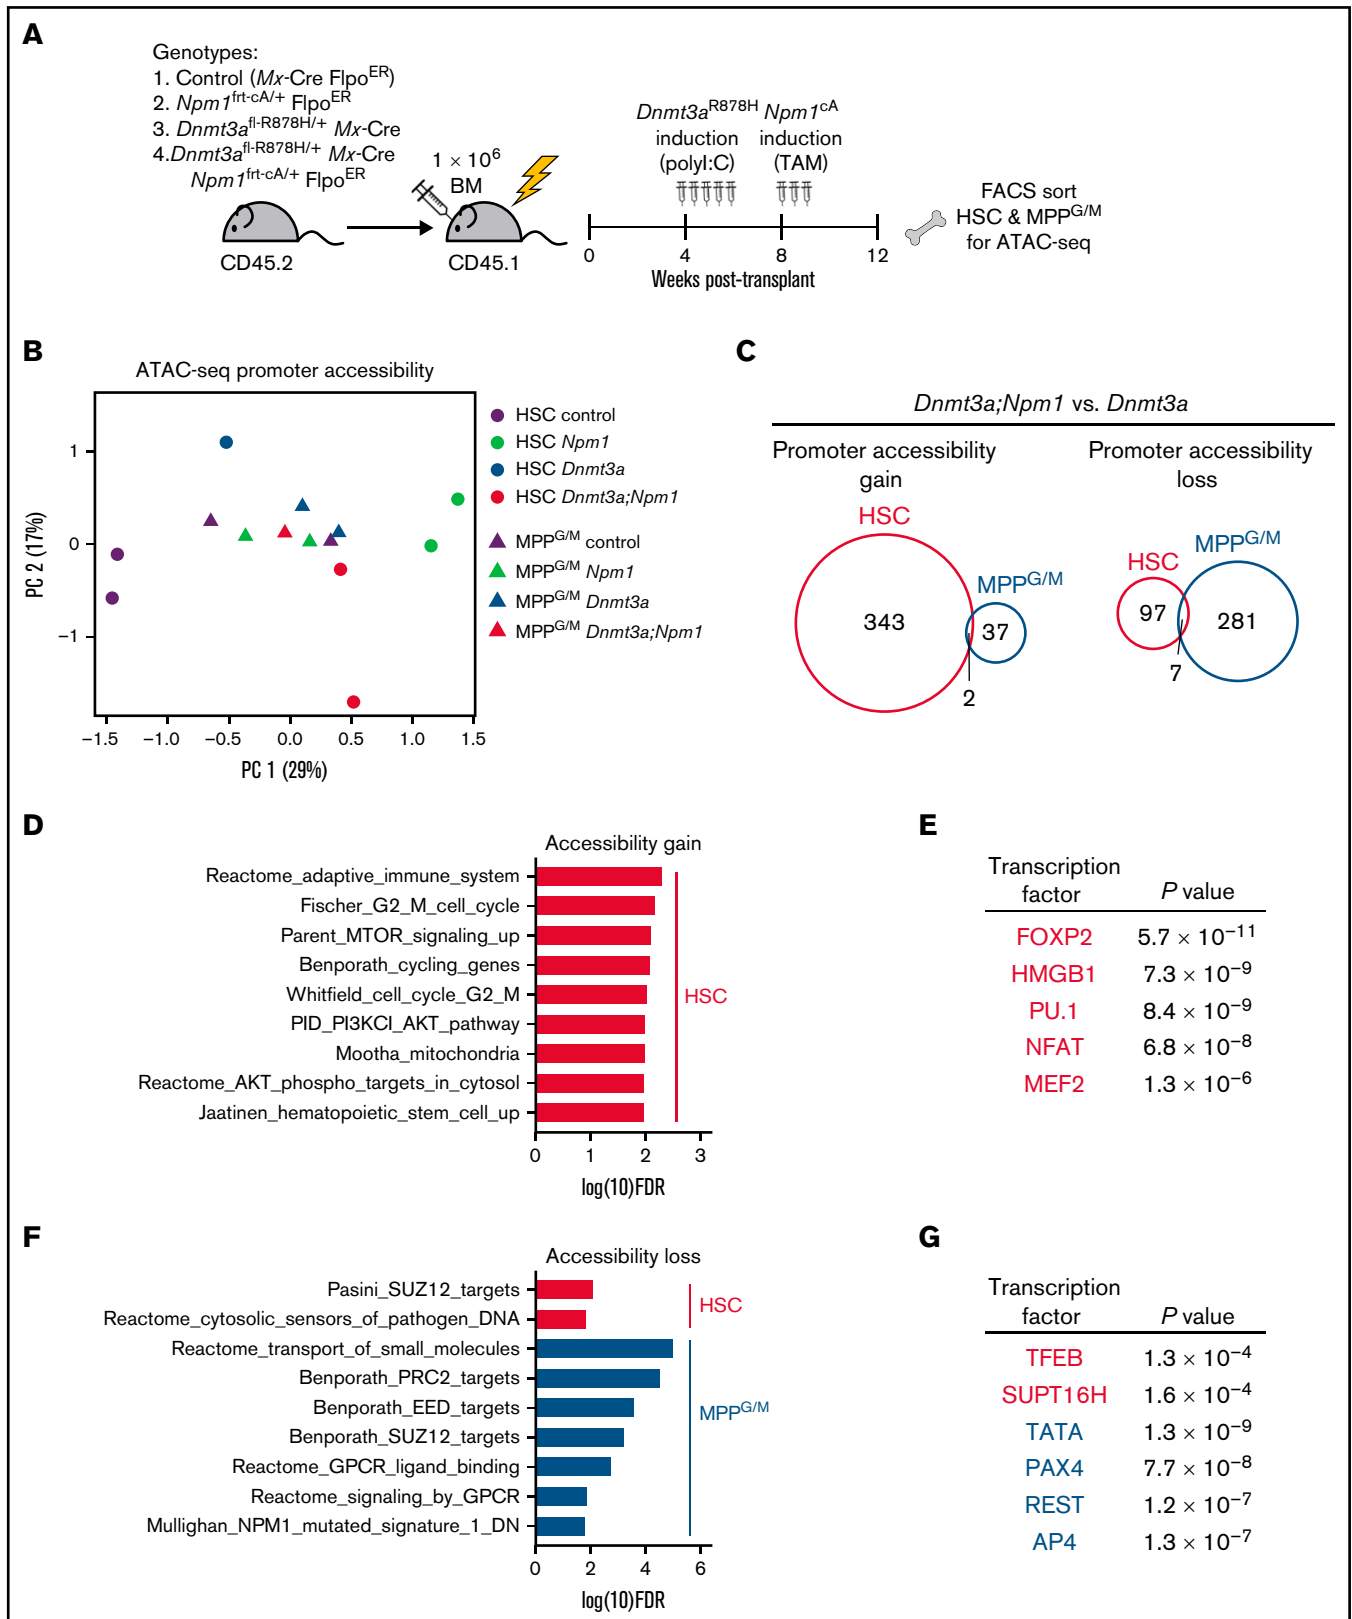

Figure 4.

molecular alterations consistent with or distinct from knockout of *Dnmt3a*. In addition, direct evaluation of the cell-context-specificity of *Dnmt3a* knockout or *Dnmt3a* mutant alleles performed by induction in multiple populations of hematopoietic stem and progenitor cells isolated from the same mice, in parallel, has not been previously described to our knowledge. Thus, our work adds robust evidence to the literature that *Dnmt3a*<sup>R878H</sup> preserves molecular self-renewal programs, confers a fitness advantage selectively in HSCs, and results in molecular signatures consistent with those observed in human *DNMT3A*-mutant HSCs.

Our data provide insight into the contexts in which *Dnmt3a*<sup>R878H</sup> provides a fitness advantage to HSCs, and in which *Dnmt3a*<sup>R878H</sup> provides a clonal advantage to mature, circulating hematopoietic cell populations. We find that *Dnmt3a*<sup>R878H/+</sup> HSCs have reduced contribution to mature PB cells upon primary transplant, consistent with an impaired differentiation phenotype reported in *Dnmt3a*<sup>-/-</sup> cells.<sup>17,30</sup> While we have not evaluated whether this decrease could be due in part to impaired homing to the BM, *Dnmt3a*<sup>-/-</sup> HSCs have previously been reported to have unaltered BM homing capacity.<sup>38</sup> After secondary transplant, we find that *Dnmt3a*<sup>R878H/+</sup> cells substantially contribute to mature BM and PB cells and outcompete their wild-type counterparts. Of note, this is distinct from the *Dnmt3a* knockout phenotype in which HSC differentiation becomes further compromised with successive transplant passages.<sup>30</sup> While the mechanism(s) by which *Dnmt3a*<sup>R878H/+</sup> HSCs overcome impaired differentiation to contribute to mature BM and PB is still actively under investigation, our data suggest that stressors such as irradiation or aging, or selection bottlenecks due to transplantation, offer sensitized conditions to deeply interrogate these mechanisms.

In their seminal study in 2014, Liran Shlush and John Dick and colleagues proposed a model wherein the cell of origin for *DNMT3A*-mutant AML is an HSC.<sup>10</sup> In this model, the initiating *DNMT3A* mutation results in an expanded pool of HSCs and downstream progenitors within which *NPM1* or other mutations are acquired to drive progression to AML. Their findings pointed to GMPs and/or multilymphoid progenitors as the likely populations which acquired an *NPM1* mutation. Murine models with orthogonal induction of the *Dnmt3a* and *Npm1*-mutant alleles and prospective isolation of cell surface-marker-defined stem and progenitor populations have allowed us to interrogate this model. We show that HSCs are the cell of origin of the initiating *Dnmt3a*<sup>R878H</sup> mutation. In addition, they are the most potent initiating cell type for myeloid malignancies arising from the subsequent acquisition of the *Npm1*<sup>C</sup> mutation, with the caveat, yet necessity, of an overnight ex vivo culture system to

induce the *Npm1*<sup>C</sup> mutation in a cell-type-specific manner. This is consistent with distinct chromatin accessibility alterations induced by the *Npm1*<sup>C</sup> mutation in *Dnmt3a*-mutant HSCs compared with downstream progeny, which suggests that activation of HSC cycling and PI3K/Akt/mTOR signaling are early, preleukemic mechanisms.

Our previous work found that during the leukemogenic progression of *Dnmt3a*;*Npm1*-mutant MDS/MPD to AML, HSC and MPP populations became depleted while myeloid-restricted progenitors such as GMPs became expanded.<sup>11</sup> Taken together with our new findings, we posit that while *Dnmt3a*-mutant HSCs have the greatest potential as an initiating cell for *Npm1*<sup>C</sup>-mediated transformation, the transformation process results in a myeloid-restricted progenitor becoming the leukemia propagating or “leukemia stem cell” population. Consistent with this concept, we observed that *Dnmt3a*;*Npm1*-mutant GMPs did not give rise to myeloid malignancies, in contrast to a recent study demonstrating that *Npm1*-mutant long-term engrafting GMPs, with or without a cooccurring *Dnmt3a* mutation, possess sufficient potency to initiate AML.<sup>19</sup> As our study transplanted 10-fold fewer numbers of GMPs into recipient animals, we may not have observed this potential due to this being a rare subset of GMPs. Engineered systems to induce mutations in a precise, cell-type-specific manner without the need for prospective isolation will be a critical technological advancement for future in vivo cell-of-origin studies. Our results suggest there may be an opportunity for therapeutic intervention to specifically target *Dnmt3a*-mutant HSCs before, or concomitant with, acquisition of additional mutations such as *Npm1*<sup>C</sup>. One challenge will be to identify a therapeutic target against *Dnmt3a*-mutant HSCs that spares wild-type HSCs. Our work supports that the sustained expression of genes regulating self-renewal may provide a therapeutic target for transient intervention, as *Dnmt3a*-mutant HSCs retain stemness and self-renewal gene signatures more prominently than that of control HSCs.

In de novo adult AML, *NPM1* is most frequently mutated with *DNMT3A*,<sup>39</sup> and the majority of *DNMT3A* mutations are found in R882, replicated by the murine R878 model used in our study. Recent analysis aimed to elucidate the prognostic impact of cooccurring *DNMT3A* and *NPM1* mutations in AML has found that *DNMT3A* mutation status does not have an overall prognostic impact<sup>40</sup>; however, *DNMT3A*<sup>mut</sup> was associated with significantly higher measurable residual disease (MRD) compared with *DNMT3A*<sup>wt</sup>, and *DNMT3A*<sup>mut</sup> patients exhibited a trend toward a greater risk of molecular relapse. Based on our results, we speculate that the cell of origin incurring and sustaining the *NPM1*

**Figure 4 (continued) *Dnmt3a*<sup>R878H/+</sup> chromatin state is altered by cooperating *Npm1*<sup>CA</sup> mutation in a cell-type-specific manner.** (A) Experimental design. (B) Principal component analysis of ATAC-seq data from HSC and MPP<sup>G/M</sup> cells with genotypes *Mx-Cre*, *Dnmt3a*<sup>R878H/+</sup>, *Npm1*<sup>CA/+</sup>, and *Dnmt3a*<sup>R878H/+</sup>;*Npm1*<sup>CA/+</sup>. Principal components were calculated based on the top 900 differentially accessible promoter peaks across all conditions, ranked by FDR. Data were collected from 2 to 3 pooled mice for each replicate (1 to 2 per condition). (C) Venn diagrams representing overlapping promoter accessibility gain (left) or loss (right) between *Dnmt3a*<sup>R878H/+</sup>;*Npm1*<sup>CA/+</sup> vs *Dnmt3a*<sup>R878H/+</sup> HSCs and MPP<sup>G/M</sup> cells. (D) Pathway enrichment of the 343 promoters with increased accessibility in *Dnmt3a*<sup>R878H/+</sup>;*Npm1*<sup>CA/+</sup> vs *Dnmt3a*<sup>R878H/+</sup> HSCs. The low number of accessible promoter gains in MPP<sup>G/M</sup> cells (39 promoters) precluded pathway enrichment analysis. (E) Transcription factor binding site enrichment in promoters with increased accessibility. (F) Pathway enrichment of the 97 promoters with decreased accessibility in *Dnmt3a*<sup>R878H/+</sup>;*Npm1*<sup>CA/+</sup> vs *Dnmt3a*<sup>R878H/+</sup> HSCs, and the 281 promoters with decreased accessibility in *Dnmt3a*<sup>R878H/+</sup>;*Npm1*<sup>CA/+</sup> vs *Dnmt3a*<sup>R878H/+</sup> MPP<sup>G/M</sup> cells. (G) Transcription factor binding site enrichment in promoters with decreased accessibility.

cooperating mutation will have an impact on disease prognosis and may be a relevant consideration when evaluating MRD.
